Generalized edema occurs in association with hydrops fetalis and in the offspring of diabetic mothers. In premature infants, edema is often a consequence of a decreased ability to excrete water or sodium, although some have considerable edema without identifiable cause. Infants with hyaline membrane disease may become edematous without heart failure. Edema of the face and scalp may be caused by pressure from the umbilical cord around the neck, and transient localized swelling of the hands or feet may similarly be due to intrauterine pressure. Edema may be associated with heart failure from congenital cardiac lesions; a lag in renal excretion of electrolytes and water may result in edema after a sudden large increase in intake of electrolytes, particularly with feeding of concentrated cow's milk formulas. High-protein formulas may also cause edema as a result of the excessive renal solute load, particularly in premature infants. It is difficult to show a relationship between low serum protein or low hemoglobin levels and the occurrence of edema in older premature infants. Edema also occurs in association with anemia and vitamin E deficiency in premature infants. Rarely, *idiopathic hypoproteinemia* with edema lasting weeks or months is observed in term infants. The cause is unclear, and the disturbance is benign. Persistent edema of one or more extremities may represent congenital lymphedema (Milroy disease) or, in females, *Turner syndrome*. Generalized edema with hypoproteinemia may be seen in the neonatal period with congenital nephrosis and rarely with Hurler syndrome or after feeding hypoallergenic formulas to infants with cystic fibrosis of the pancreas. *Sclerema* is described in

Chapter 637 .

HYPOCALCEMIA (TETANY) (see Chapters 44.11 and 48.9)

Metabolic Bone Disease.

Metabolic bone disease is a common complication in very low birthweight preterm infants. The smallest sickest infants are at greatest risk. Progressive osteopenia with demineralized bones and occasionally pathologic fractures may develop. The major cause is inadequate intake of calcium to meet the demands for growth. Poor intake of phosphorus and vitamin D are additional risk factors. Contributing factors include prolonged parenteral nutrition, vitamin D and calcium malabsorption, intake of unsupplemented human milk, immobilization, and calcium loss from chronic diuretic use. The serum alkaline phosphatase level is used to monitor metabolic bone disease and can be over 1,000?U/L in severe cases. Fortified human milk and formulas designed for preterm infants provide improved intake of calcium, phosphorus, and vitamin D; promote bone mineralization; and may prevent metabolic bone disease. Many extremely low birthweight infants will require additional oral supplements of calcium, phosphorus, and vitamin D. Treatment of fractures requires immobilization and administration of calcium and, if needed, phosphorus (for hypophosphatemia) and vitamin D (not more than 1,000?IU/day unless severe cholestasis or vitamin D resistance is present). See also Chapters 44.10 , 44.11 , 45.5 , 45.7 , 48.9 , 696 , 697 .

HYPOMAGNESEMIA

Rarely, hypomagnesemia of unknown cause may occur in newborn infants, usually in association with hypocalcemia. It may also be associated with insufficient stores of skeletal magnesium secondary to deficient placental transfer, decreased intestinal absorption, neonatal hypoparathyroidism, hyperphosphatemia, renal loss (primary or drugs, e.g., amphotericin B), a defect in magnesium and calcium homeostasis, or iatrogenic deficiency caused by loss incurred during exchange transfusion or insufficient replacement during total intravenous alimentation. Infants of diabetic mothers may have serum magnesium levels that are lower than normal. The clinical manifestations of hypomagnesemia are indistinguishable from those of hypocalcemia and tetany and may, in fact, contribute to the accompanying hypocalcemia.

Hypomagnesemia occurs when serum magnesium levels fall below 1.5?mg/dL (0.62?mmol/L), although clinical signs do not usually develop until serum magnesium levels fall below 1.2?mg/dL. During exchange transfusion with citrated blood, which is low in magnesium because of binding by citrate, serum magnesium decreases about 0.5?mg/dL (0.2?mmol/L); approximately 10 days is required for return to normal. In non-iatrogenic hypomagnesemia, the serum magnesium level may be less than 0.5?mg/dL. Serum calcium in either instance is usually at levels noted in hypocalcemic tetany, but the serum phosphorus value is normal or high. Because the hypocalcemia accompanying hypomagnesemia is inadequately corrected by administering calcium alone, hypomagnesemia should also be suspected in any patient with tetany not responding to calcium therapy.

Immediate *treatment* consists of intramuscular injection of magnesium sulfate. For newborn infants, 0.25?mL/kg of a 50% solution daily usually suffices. The accompanying hypocalcemia usually corrects itself as the hypomagnesemia is relieved. The same daily dose can be given for oral maintenance therapy. Four to five times higher doses may be required in malabsorptive states. In most cases, the metabolic defect is transient, and treatment can be discontinued after 1–2 wk. A few patients appear to have a permanent form of the disease that requires continuous oral supplementation with magnesium to prevent recurrence of hypomagnesemia. No residual damage to the central nervous system is evident after prompt treatment.

HYPERMAGNESEMIA

Hypermagnesemia may occur in newborn infants of mothers treated with magnesium sulfate during labor. At high serum levels the central nervous system is depressed, and infants have profound respiratory depression requiring mechanical ventilation. Lower levels may result in hypoventilation, lethargy, flaccidity, hyporeflexia, and poor sucking. Hypermagnesemia may be associated with failure to pass meconium (meconium plug syndrome). The upper limit of normal magnesium is 2.8?mg/dL (1.15?mmol/L), but serious symptoms rarely occur at levels below 5?mg/dL (2.1?mmol/L). In most cases, no specific therapy (beyond supportive care and maintenance of respiratory support) is required. Intravenous calcium and diuresis will reduce magnesium levels. In rare cases, exchange transfusion has been used for rapid removal of magnesium ion from the blood.

OTHER METABOLIC DISEASES

A number of inborn errors of metabolism may be manifested during the neonatal period, including phenylketonuria, galactosemia, the urea cycle defects, methylmalonicacidemia, and maple syrup urine disease (see Chapters 74 to 76). Pyridoxine deficiency and dependence are considered in Chapter 44.6 .

SUBSTANCE ABUSE AND NEONATAL ABSTINENCE (WITHDRAWAL)

Substance abuse during pregnancy is a serious problem for both the mother and her newborn. The mother may suffer adverse consequences of her addiction, including episodes of drug withdrawal during pregnancy and illnesses related to high-risk behavior. Effects on the fetus and newborn include chronic or intermittent drug exposure, acute withdrawal shortly after birth, and long-term effects on physical growth and neurodevelopment. Because infants with in utero drug exposure often have social and environmental risk factors and may have been exposed to multiple substances, it may be difficult to evaluate the effects of specific in utero drug exposure on long-term neurodevelopmental outcome.

Pregnancy in women who use illegal drugs or alcohol is, by definition, high risk. Substance misuse in pregnant women is a difficult problem to address from both medical and social aspects. Prenatal care is usually inadequate, and these women have a higher incidence of sexually transmitted diseases, including syphilis, HIV, and hepatitis. In addition, the risk of preterm labor, intrauterine growth restriction, premature rupture of membranes, and perinatal morbidity and mortality is higher. Physiologic addiction to narcotics occurs in most infants born to actively addicted

mothers because opiates cross the placenta. Withdrawal may be manifested even before birth by increased activity of the fetus when the mother feels a need for the drug or withdrawal symptoms develop. Heroin and methadone are the drugs most frequently associated with withdrawal syndromes, but such syndromes may also occur with alcohol, phenobarbital, pentazocine, codeine, propoxyphene, hydroxyzine, amphetamines, neuroleptics, antidepressants, and benzodiazepines.

Heroin addiction results in a 50% incidence of low-birthweight infants, half of whom are small for gestational age. Chronic infections, maternal undernutrition, and a direct fetal growth-inhibiting effect are possible causes. The rate of stillbirths is increased, but not the incidence of congenital anomalies. *Clinical manifestations* of withdrawal occur in 50–75% of infants, usually beginning within the 1st 48?hr, depending on the daily maternal dose (<6?mg/24?hr is associated with no or mild symptoms), the duration of addiction (>1 yr has a >70% incidence of withdrawal), and the time of the last maternal dose (the incidence is higher if the last dose was taken within 24?hr of birth). Rarely, symptoms may appear as late as 4–6 wk of age. The incidence of hyaline membrane disease and hyperbilirubinemia may be decreased in preterm infants of heroin users; accelerated production of pulmonary surfactant may explain the former, and enzyme induction of hepatic glucuronyl transferase the latter.

Tremors and hyperirritability are the most prominent symptoms. The tremors may be fine or jittery and indistinguishable from those of hypoglycemia, but they are more often coarse, “flapping,” and bilateral; the limbs are frequently rigid, hyperreflexic, and resistant to flexion and extension. Irritability and hyperactivity are generally marked and may lead to skin abrasions. Other signs include wakefulness, hyperacusis, hypertonicity, tachypnea, diarrhea, vomiting, high-pitched cry, fist sucking, poor feeding with weight loss (disorganized sucking), and fever. Sneezing, yawning, hiccups, myoclonic jerks, convulsions, abnormal sleep cycles, nasal stuffiness, apnea, flushing alternating rapidly with pallor, and lacrimation are less common. The risk of sudden infant death syndrome is increased. The *diagnosis* is generally established by the history and clinical findings. Examining the urine for opiates may reveal only low levels during withdrawal, but quinine, which is often mixed with heroin, may be present in higher concentrations. Meconium testing is more accurate than neonatal urine drug testing. Hypoglycemia and hypocalcemia should be excluded.

Methadone addiction is associated with severe withdrawal symptoms, the incidence varying from 20–90%. In general, mothers taking methadone have better prenatal care than those taking heroin; however, these mothers have a high incidence of polysubstance abuse, including alcohol, barbiturates, and tranquilizers, and they are often heavy smokers. The incidence of congenital anomalies is not increased. The average birthweight of infants of mothers taking methadone is higher than that of infants of heroin-addicted mothers; the *clinical manifestations* are similar except that the former group has a higher incidence of seizures (10–20%) and the late onset (2–6 wk of age) of symptoms and signs. Unfortunately, some women continue to abuse heroin, even if they enter a methadone program. Neonates born to these women are more likely to be preterm and/or low birthweight than those born to women who stop using heroin. They are also more likely to suffer withdrawal and have a higher risk of neonatal mortality.

Alcohol withdrawal is uncommon. Infants of women who have been drinking immediately before delivery may have alcohol on their breath for several hours because it rapidly crosses the placenta and blood levels in the infant are similar to those in the mother. Hypoglycemia and acidosis may be present. Infants in whom withdrawal symptoms develop often become agitated and hyperactive, with marked tremors lasting 72?hr, followed by about 48?hr of lethargy before return to normal activity. Seizures may develop.

Phenobarbital withdrawal usually occurs in full-term, appropriate for gestational age infants of addicted mothers. Symptoms begin at a median age of 7 days (range, 2–14 days). Infants may have a brief acute stage consisting of irritability, constant crying, sleeplessness, hiccups, and mouthing movements, followed by a subacute stage consisting of voracious appetite, frequent regurgitation and gagging, episodic irritability, hyperacusis, sweating, and a disturbed sleep pattern, all of which may last 2–4 mo.

Cocaine abuse in pregnant women is common, but withdrawal in their infants is unusual; the pregnancy may be complicated by premature labor, abruptio placentae, and fetal asphyxia. Infants may have intrauterine growth restriction and neurobehavioral deficits characterized by impaired state regulation, impaired auditory information processing, developmental delay, and learning disabilities. At 24 mo of age, they score lower on the mental scale of the Bayley score and are twice as likely to have developmental delay. Family disorganization, polysubstance abuse, sexually transmitted diseases, and child abuse and neglect may also affect these unfortunate families.

Treatment.

Infants who are undergoing withdrawal require care in a quiet environment with reduction of external stimuli and swaddling. Not all infants require drug therapy. Therapy is indicated for seizures, for diarrhea, or for such irritability that normal sleep and feeding patterns are disturbed and weight gain is poor. *Treatment* of heroin and methadone withdrawal has been successful with various combinations of narcotics, sedatives, and hypnotics. Methadone withdrawal may require larger amounts of medication for longer periods to control clinical manifestations than are needed for heroin withdrawal. Phenobarbital, 5–10?mg/kg/24?hr in three to four divided doses, can effectively reduce irritability and prevent seizures. Paregoric at a beginning dose of 0.05–0.1?mL/kg is given every 3–4?hr and increased by 0.05?mL every 4?hr if necessary, depending on the size and response of the infant. Paregoric abolishes most withdrawal symptoms, especially diarrhea. Tincture of opium (10?mg/mL) diluted 25-fold results in the same morphine equivalency as paregoric. The recommended dose of diluted tincture of opium is 0.1?mL/kg (?2 drops/kg) with feedings every 4?hr. The dose may be increased by 2 drops every 4?hr if needed. The dose and duration of therapy may be adjusted according to the clinical response. Parenteral administration of fluids may be necessary to prevent aspiration or dehydration until the symptoms are brought under control.

Current mortality from withdrawal is under 5% and may be negligible with early recognition and treatment. The *prognosis* for normal development is affected by the

adverse circumstances of high-risk pregnancy and delivery and by the environment to which the infant is returned after recovery, as well as by the effects of the particular drug on fetal and subsequent neonatal development.

Fetal Alcohol Syndrome.

High levels of alcohol ingestion during pregnancy can be damaging to embryonic and fetal development. A specific pattern of malformation identified as the *fetal alcohol syndrome* has been documented, and major and minor components of the syndrome are expressed in 1–2 infants/1,000 live births (Table 95–1). Both moderate and high levels of alcohol intake during early pregnancy may result in alterations in growth and morphogenesis of the fetus; the greater the intake, the more severe the signs. Infants born to heavy drinkers have twice the risk of abnormality as those born to moderate drinkers; 32% of infants born to heavy drinkers had congenital anomalies as compared with 9% in the abstinent and 14% in the moderate group. Additional maternal risk factors associated with fetal alcohol syndrome are advanced maternal age, low socioeconomic status, poor psychologic indicators, and binge drinking.

Characteristics of fetal alcohol syndrome include (1) prenatal onset and persistence of growth deficiency for length, weight, and head circumference; (2) facial abnormalities, including short palpebral fissures, epicanthal folds, maxillary hypoplasia, micrognathia, and a thin upper lip; (3) cardiac defects, primarily septal defects; (4) minor joint and limb abnormalities, including some restriction of movement and altered palmar crease patterns; and (5) delayed development and mental deficiency varying from borderline to severe (see Table 95–1). Fetal alcohol syndrome is a common identifiable cause of mental retardation. The severity of dysmorphogenesis may range from severely affected infants with full manifestations of fetal alcohol syndrome to those mildly affected with only a few manifestations.

The detrimental effects may be due to the alcohol itself or to one of its breakdown products. Some evidence suggests that alcohol may impair placental transfer of essential amino acids and zinc, both necessary for protein synthesis, which may account for the intrauterine growth restriction.

TABLE 95-1 -- Fetal Alcohol Syndrome Surveillance Network Case Definition Categories

Case Definition Category	Phenotype Positive		
	Face	***Central Nervous System***	***Growth***
Confirmed fetal alcohol syndrome (FAS) phenotype with or without maternal alcohol exposure[*]	Abnormal facial features consistent with FAS as reported by a physician	Frontal-occipital circumference =10th percentile at birth or any age	Intrauterine weight or height corrected for gestational age =10th percentile
	or	*or*	*or*
	Two of the following: Short palpebral fissures Abnormal philtrum Thin upper lip	Standardized measure of intellectual function =1 SD below the mean	Postnatal weight or height =10th percentile for age
		or	*or*
		Standardized measure of developmental delay =1 SD below the mean	Postnatal weight for height =10th percentile
		or	
		Developmental delay or mental retardation diagnosed by a qualified examiner (e.g., psychologist or physician)	
		or	
		Attention deficit disorder diagnosed by a qualified evaluator	
Probable FAS phenotype with or without maternal alcohol exposure[*]	Required; facial features same as above	Must meet either CNS or growth criteria as outlined above	

From Fetal alcohol syndrome—Alaska, Arizona, and New York, 1995–1997. MMWR Morb Mortal Wkly Rep 2002;51:433.

* *Documentation in the records of some level of maternal alcohol use during the index pregnancy.*

Treatment of these infants is difficult because no specific therapy exists. These infants may remain hypotonic and tremulous despite sedation, and the prognosis is poor. Counseling with regard to recurrence is important. *Prevention* is achieved by eliminating alcohol intake after conception.

Chapter 96 - The Endocrine System

Barbara J. Stoll
Robert M. Kliegman

The endocrinopathies are discussed in Part XXV . This chapter focuses on endocrine disturbances that may be identified at birth or during the 1st mo of life.

Pituitary dwarfism is not usually apparent at birth, although panhypopituitary male infants may have neonatal hypoglycemia, hyperbilirubinemia, and micropenis. Conversely, constitutional dwarfs usually have length and weight consistent with prematurity when born after a normal gestational period; otherwise, their physical appearance is normal.

Primary hypothyroidism occurs in approximately 1/4,000 births. Because most of these infants are asymptomatic at birth, all states screen for this serious and treatable disease. *Thyroid deficiency* may also be apparent at birth in genetically determined **cretinism** or in infants of mothers treated with thiouracil or its derivatives during pregnancy. Constipation, prolonged jaundice, goiter, lethargy, or poor peripheral circulation as shown by persistently mottled skin or cold extremities should suggest cretinism. Early diagnosis plus treatment of congenital deficiency of thyroid hormone improves intellectual outcome and is facilitated by screening all newborn infants for this deficiency. Transient hypothyroxinemia of prematurity is most common in ill infants of very low birthweight. These infants are probably chemically euthyroid as suggested by normal levels of serum thyrotropin and other tests of the pituitary-hypothalamic axis. Because the relationship between low thyroid levels and neurodevelopmental outcome is unclear, it remains uncertain whether premature infants with this transient problem should be treated with thyroid hormone.

Temporary *hyperthyroidism* may occur at birth in infants of mothers with hyperthyroidism or in infants whose mothers have been receiving thyroid medication.

Transient *hypoparathyroidism* may be manifested as tetany of the newborn (Chapter 565).

The *adrenal glands* are subject to numerous disturbances, which may become apparent and require lifesaving treatment during the neonatal period. Acute adrenal *hemorrhage* and failure may occur after breech or other traumatic deliveries or in association with overwhelming infection. *Congenital adrenal hyperplasia* is suggested by vomiting, diarrhea, dehydration, hyperkalemia, hyponatremia, shock, ambiguous genitals, or clitoral enlargement. Some infants have ambiguous genitals and hypertension. Because the condition is genetically determined, newborn siblings of patients with the salt-losing variety of adrenocortical hyperplasia should be closely observed for manifestations of adrenal insufficiency. Newborn screening and early diagnosis and therapy for this disorder may prevent severe salt wasting and adverse outcomes.

Congenitally hypoplastic adrenal glands may also give rise to adrenal insufficiency during the first few weeks of life.

Female infants with webbing of the neck, lymphangiectatic edema, hypoplasia of the nipples, cutis laxa, low hairline at the nape of the neck, low-set ears, high-arched palate, deformities of the nails, cubitus valgus, and other anomalies should be suspected of having *gonadal dysgenesis*.

Transient *diabetes mellitus* (Chapter 583) is rare and is encountered only in newborns. It is usually manifested as dehydration, loss of weight, or acidosis in small for gestational age infants.

96.1 Infants of Diabetic Mothers

Control of diabetes mellitus with insulin has led to improved outcomes in diabetic women who bear children. Their infants and the infants of women in whom diabetes later develops share certain distinctive morphologic characteristics, macrosomia, and a high risk of morbidity. Diabetic mothers have a high incidence of polyhydramnios, preeclampsia, pyelonephritis, preterm labor, and chronic hypertension; their fetal mortality rate, which is high at all gestational ages, especially after 32 wk, is greater than that of nondiabetic mothers. Fetal loss throughout pregnancy is associated with poorly controlled maternal diabetes (especially ketoacidosis) and congenital anomalies. Most infants born to diabetic mothers are large for gestational age. If the diabetes is complicated by vascular disease, infants may be growth restricted, especially those born after 37 wk gestation. The neonatal mortality rate is over five times that of infants of nondiabetic mothers and is higher at all gestational ages and in every birthweight for gestational age category.

Pathophysiology.

The probable pathogenic sequence is that maternal hyperglycemia causes fetal hyperglycemia, and the fetal pancreatic response leads to fetal hyperinsulinemia; fetal hyperinsulinemia and hyperglycemia then cause increased hepatic glucose uptake and glycogen synthesis, accelerated lipogenesis, and augmented protein synthesis. Related pathologic findings are hypertrophy and hyperplasia of the pancreatic islets with a disproportionate increase in the number of ß cells, increased weight of the placenta and infant organs except for the brain, myocardial hypertrophy, increased amount of cytoplasm in liver cells, and extramedullary hematopoiesis. Hyperinsulinism and hyperglycemia produce fetal acidosis, which may result in an increased rate of stillbirth. Separation of the placenta at birth suddenly interrupts glucose infusion into the neonate without a proportional effect on the hyperinsulinism, and hypoglycemia and attenuated lipolysis develop during the

first hours after birth.

Hyperinsulinemia has been documented in infants of gestational diabetic mothers and in those of insulin-dependent diabetic mothers without insulin antibodies. The former group also has significantly higher fasting plasma insulin levels than normal newborns do despite similar glucose levels; they respond to glucose with an abnormally prompt elevation in plasma insulin and assimilate a glucose load more rapidly. After arginine administration, they also have an enhanced insulin response and increased disappearance rates of glucose in comparison to normal infants. In contrast, fasting glucose production and utilization rates are diminished. The lower free fatty acid levels in infants of insulin-dependent diabetic mothers probably also reflect their hyperinsulinemia. With good prenatal diabetic control, the incidence of macrosomia and hypoglycemia has decreased.

Although hyperinsulinism is probably the main cause of hypoglycemia, the diminished epinephrine and glucagon responses that occur may be contributing factors. Cortisol and human growth hormone levels are normal. Congenital anomalies correlate with poor metabolic control during the periconception and organogenesis periods and may be due to hyperglycemia-induced teratogenesis.

Clinical Manifestations.

Infants of diabetic and gestational diabetic mothers often bear a surprising resemblance to each other (Fig. 96–1). They tend to be large and plump as a result of increased body fat and enlarged viscera, with puffy, plethoric facies resembling that of patients who have been receiving

Figure 96.1-1 Large, plump, plethoric infant of a gestational diabetic mother. The baby was born at 38 wk of gestation but weighed 9?lb, 11 oz (4,408?g). Mild respiratory distress was the only symptom other than appearance.

corticosteroids. These infants may, however, also be of normal or low birthweight, particularly if delivered before term or the mother has associated vascular disease.

Hypoglycemia develops in about 25–50% of infants of diabetic mothers and 15–25% of infants of mothers with gestational diabetes, but only a small percentage of these infants become symptomatic. The probability of hypoglycemia developing in the infant increases, and glucose levels are likely to be lower at higher cord or maternal fasting blood glucose levels. The nadir in an infant's blood glucose concentration is usually reached between 1 and 3?hr; spontaneous recovery may begin by 4–6?hr.

The infants tend to be jumpy, tremulous, and hyperexcitable during the 1st 3 days of life, although hypotonia, lethargy, and poor sucking may also occur. They may have any of the diverse manifestations of hypoglycemia. Early appearance of these signs is more likely to be related to hypoglycemia and later appearance related to hypocalcemia; these abnormalities may also occur together. Perinatal asphyxia or hyperbilirubinemia may produce similar signs. Hypomagnesemia may be associated with the hypocalcemia.

Tachypnea develops in many infants of diabetic mothers during the 1st 2 days of life and may be a manifestation of hypoglycemia, hypothermia, polycythemia, cardiac failure, transient tachypnea, or cerebral edema from birth trauma or asphyxia. Infants of diabetic mothers have a higher incidence of respiratory distress syndrome than do infants of nondiabetic mothers born at comparable gestational age; the greater incidence is possibly related to an antagonistic effect of insulin on stimulation of surfactant synthesis by cortisol.

Cardiomegaly is common (30%), and heart failure occurs in 5–10% of infants of diabetic mothers. Asymmetric septal hypertrophy may occur and become manifested similar to idiopathic hypertrophic subaortic stenosis. Inotropic agents worsen the obstruction and are contraindicated. Birth trauma is also a common sequela of fetal macrosomia.

Neurologic development and ossification centers tend to be immature and correlate with brain size (which is not increased) and gestational age rather than total body weight. In addition, these infants have an increased incidence of hyperbilirubinemia, polycythemia, and renal vein thrombosis; the latter should be suspected in infants with a flank mass, hematuria, and thrombocytopenia.

The incidence of congenital anomalies is increased threefold in infants of diabetic mothers; cardiac malformations (ventricular or atrial septal defect, transposition of the great vessels, truncus arteriosus, double-outlet right ventricle, coarctation of the aorta) and lumbosacral agenesis are most common. Additional anomalies include neural tube defects, hydronephrosis, renal agenesis and dysplasia, duodenal or anorectal atresia, situs inversus, double ureter, and holoprosencephaly. These infants may also develop abdominal distention caused by a transient delay in development of the left side of the colon, the *small left colon syndrome.*

Prognosis.

The subsequent incidence of diabetes mellitus in infants of diabetic mothers is increased in comparison to that of the general population. Physical development is normal, but oversized infants may be predisposed to childhood obesity that may extend into adult life. Disagreement persists about whether these infants have a slightly increased risk of impaired intellectual development unrelated to hypoglycemia; symptomatic hypoglycemia increases the risk, as does maternal ketonuria.

Treatment.

Treatment of infants of diabetic mothers should be initiated before birth by frequent prenatal evaluation of all pregnant women with overt or gestational diabetes, by evaluation of fetal maturity, by biophysical profile, by Doppler velocimetry, and by planning the delivery of these infants in hospitals where expert obstetric and pediatric care is continuously available. Periconception glucose control reduces the risk of anomalies, and glucose control during labor reduces the incidence of neonatal hypoglycemia. Women with type 1 diabetes who have tight glucose control during pregnancy (average daily glucose levels <95?mg/dL) deliver infants with birthweights

and anthropomorphic features that are similar to those of infants of nondiabetic mothers. Women with gestational diabetes may be treated successfully with glyburide, which may not cross the placenta. In these mothers, the incidence of macrosomia and neonatal hypoglycemia was similar to that in mothers with insulin-treated gestational diabetes. Regardless of size, all infants of diabetic mothers should initially receive intensive observation and care. Asymptomatic infants should have a blood glucose determination within 1?hr of birth and then every hour for the next 6–8?hr; if clinically well and normoglycemic, oral or gavage feeding with breast milk or formula should be started as soon as possible and continued at 3?hr intervals. If any question arises about an infant's ability to tolerate oral feeding, the feeding should be discontinued and glucose given by peripheral intravenous infusion at a rate of 4–8?mg/kg/min. Hypoglycemia should be treated, even in asymptomatic infants, by frequent feeding and/or intravenous infusion of glucose. Bolus injections of hypertonic glucose should be avoided because they may cause further hyperinsulinemia and potentially produce rebound hypoglycemia. Managing hypoglycemia in sick or symptomatic infants is discussed in the following section. For treatment of *hypocalcemia* and *hypomagnesemia,* see Chapter 95 ; for *hyaline membrane disease* treatment, see Chapter 90.3 ; for treatment of *polycythemia,* see Chapter 92.3 .

96.2 Hypoglycemia (see also Chapter 88)

Hypoglycemia is present when serum glucose levels are significantly lower than the range in postnatal age-matched normal infants. Although hypoglycemia may also be defined as the presence of neurologic (lethargy, coma, apnea, seizures) or sympathomimetic (pallor, palpitations, diaphoresis) manifestations

that respond to glucose, many neonates with low serum glucose levels are asymptomatic, whereas normoglycemic infants may have nonspecific signs of hypoglycemia.

The *incidence of hypoglycemia* varies with the definition, population, method and timing of feeding, and type of glucose assay (serum levels are higher than whole blood values) (Fig. 96–2). Early feeding decreases the incidence, whereas prematurity, hypothermia, hypoxia, maternal diabetes, maternal glucose infusion in labor, and intrauterine growth restriction (IUGR) increase the incidence of hypoglycemia. Serum glucose levels decline after birth until 1–3?hr of age, when levels spontaneously increase in normal infants. In healthy term infants, serum glucose values are rarely less than 35?mg/dL between 1 and 3?hr of life, less than 40?mg/dL from 3 to 24?hr, and less than 45?mg/dL (2.5?mmol/L) after 24?hr. Although previous studies, performed when premature infants were not fed on the 1st day of life, suggested that premature infants have statistically lower glucose levels than term infants do and that preterm infants may be unaffected by low glucose values, evidence does not support these conclusions. Both premature and full-term infants are at risk for serious neurodevelopmental deficits from equally low glucose levels. This risk is related to the depth and duration of the hypoglycemia.

Several pathophysiologic groups of *neonatal infants are at high risk for hypoglycemia*. (1) Hyperinsulinism: Infants of mothers with diabetes mellitus or gestational diabetes and infants with severe erythroblastosis fetalis, insulinomas, leucine sensitivity with hyperammonemia, familial or sporadic hyperinsulinemia, Beckwith syndrome (see later), and panhypopituitarism have hyperinsulinism. *Familial hyperinsulinemic hypoglycemia* (previously called nesidioblastosis) may be an autosomal recessive disease characterized by excessive fetal growth and severe neonatal hypoglycemia, often unresponsive to medical management. This severe form is due to defects in either of the two components of the islet ß cell K_{ATP} channel (either the sulfonylurea receptor or the Kir6.2 inward rectifier K^+ channel). A milder autosomal dominant form with delayed onset has an unknown

Figure 96.2-2 Incidence of hypoglycemia by birthweight, gestational age, and intrauterine growth. (From Lubchenco LO, Bard H: Incidence of hypoglycemia in newborn infants classified by birth weight and gestational age. *Pediatrics* 1971;47:832.)

cause. Familial or sporadic hyperammonemic hyperinsulinemia is due to a mutation of the glutamate dehydrogenase gene (increased glutamate oxidation in the ß cell releases insulin). (2) IUGR/prematurity: Infants with IUGR or those who are preterm may have experienced intrauterine malnutrition resulting in reduced hepatic glycogen stores and total body fat, especially the smaller of discordant twins (if discordant by 25% or more in weight with a weight <2.0?kg). Other factors in the development of hypoglycemia in this group include impaired gluconeogenesis, diminished free fatty acid oxidation, low cortisol production rates, and possibly increased insulin levels and decreased output of epinephrine in response to hypoglycemia. (3) Increased metabolic demands: Hypoglycemia may develop in very immature or severely ill infants as a result of increased metabolic needs disproportionate to substrate stores and the calories supplied; low-birthweight infants with respiratory distress syndrome, perinatal asphyxia, polycythemia, hypothermia, and systemic infections, as well as infants in heart failure with cyanotic congenital heart disease, are at increased risk. Interruption of intravenous infusions, particularly those with high glucose concentrations, may also result in a precipitous onset of hypoglycemia. (4) Genetic causes: Rare infants with genetic or primary metabolic defects, such as galactosemia, glycogen storage disease, fructose intolerance, propionicacidemia, methylmalonicacidemia, tyrosinemia, maple syrup urine disease, and long- or medium-chain acyl-CoA dehydrogenase deficiency, are also susceptible.

Clinical Manifestations.

In contrast to the frequency of chemical hypoglycemia, the incidence of symptomatic hypoglycemia is highest in small for gestational age infants (see Fig. 96–2). These infants usually fall into category 2 or 3 of the earlier pathophysiologic groupings, and some are referred to as having *transient symptomatic idiopathic neonatal hypoglycemia*. Because many of the symptoms also occur together with other conditions such as infections—especially sepsis and meningitis; central nervous system anomalies, hemorrhage, or edema; hypocalcemia and hypomagnesemia; asphyxia; drug withdrawal; apnea of prematurity; congenital heart disease; or polycythemia—and because some may be seen in normoglycemic well infants, the exact incidence of symptomatic hypoglycemia has been difficult to establish. It probably varies between 1 and 3 per 1,000 live births and affects about 5–15% of growth-restricted infants.

The onset of symptoms varies from a few hours to a week after birth. In approximate order of frequency, symptoms include jitteriness or tremors, apathy, episodes of cyanosis, convulsions, intermittent apneic spells or tachypnea, weak or high-pitched cry, limpness or lethargy, difficulty feeding, and eye rolling. Episodes of sweating, sudden pallor, hypothermia, and cardiac arrest and failure also occur. Frequently, a clustering of episodic symptoms may be noted. Because these clinical manifestations may result from various causes, it is critical to measure serum glucose levels and determine whether they disappear with the administration of sufficient glucose to raise the blood sugar to normal levels; if they do not, other diagnoses must be considered.

Treatment.

When symptoms other than seizures are present, an intravenous bolus of 200?mg/kg (2?mL/kg) of 10% glucose is effective in elevating the blood glucose concentration. In the presence of convulsions, 4?mL/kg of 10% glucose as a bolus injection is indicated.

After initial therapy, a glucose infusion should be given at 8?mg/kg/min. If hypoglycemia recurs, the infusion rate and concentration should be increased until 15–20% glucose is used. If intravenous infusions of 20% glucose are inadequate to eliminate symptoms and maintain constant normal serum glucose concentrations, hyperinsulinemia is probably present and diazoxide should be administered. If the diazoxide is unsuccessful,

octreotide may be useful; many infants with severe persistent hyperinsulinemic hypoglycemia undergo subtotal pancreatectomy. The serum glucose level should be measured every 2?hr after initiating therapy until several determinations are above 40?mg/dL. Subsequently, levels should be measured every 4–6?hr and the treatment gradually reduced and finally discontinued when the serum glucose value has been in the normal range and the baby asymptomatic for 24–48?hr. Treatment is usually necessary for a few days to a week, rarely for several weeks.

Infants at increased risk for hypoglycemia should have their serum glucose measured within 1?hr of birth, every 1–2?hr for the 1st 6–8?hr, and then every 4–6?hr until 24?hr of life. Normoglycemic high-risk infants should receive oral or gavage feeding with human milk or formula started at 1–3?hr of age and continued at 2–3?hr intervals for 24–48?hr. An intravenous infusion of glucose at 4?mg/kg/min should be provided if oral feedings are poorly tolerated or if asymptomatic transient neonatal hypoglycemia develops.

Prognosis.

The prognosis is good in asymptomatic patients with hypoglycemia of short duration. Hypoglycemia recurs in 10–15% of infants after adequate treatment. Recurrence is more common if intravenous fluids are extravasated or discontinued too rapidly before oral feedings are well tolerated. Children in whom ketotic hypoglycemia later develops have an increased incidence of neonatal hypoglycemia. The prognosis for normal intellectual function must be guarded because prolonged, recurrent, and severe symptomatic hypoglycemia is associated with neurologic sequelae. Symptomatic infants with hypoglycemia, particularly low-birthweight infants, those with persistent hyperinsulinemic hypoglycemia, and infants of diabetic mothers, have a poorer prognosis for subsequent normal intellectual development than asymptomatic infants do.

HYPOGLYCEMIA WITH MACROGLOSSIA (BECKWITH-WIEDEMANN SYNDROME)

This syndrome includes intractable neonatal hypoglycemia occurring in infants with macroglossia, large size, visceromegaly, mild microcephaly, omphalocele, facial nevus flammeus, a characteristic earlobe crease, an increased risk of tumors (Wilms, hepatoblastoma, gonadoblastoma), and renal medullary dysplasia. The visceromegaly chiefly involves the liver and the kidneys and is due to noncystic hyperplasia. Some infants are also polycythemic, and hyperinsulinemia has been demonstrated. Some infants with Beckwith syndrome have a partial duplication of chromosome 11p, a region that encodes the insulin-like growth factor II gene. Though usually sporadic, familial inheritance has been noted. Treatment is the same as that for hyperinsulinemic hypoglycemia, but in this syndrome, the hypoglycemia may be severe and persist for several months. The prognosis is poor if symptomatic hypoglycemia is severe. Many may be managed medically for the hyperinsulinemic hypoglycemia, but those refractory to such treatment may require subtotal pancreatectomy.

Severe hypoglycemia has also been demonstrated in extremely high birthweight infants who do not have the anomalies present in Beckwith syndrome. These *infant giants* weigh from 3.8 to 5.3?kg, and in some, pancreatic hyperplasia has been described.

Chapter 97 - Dysmorphology

Kenneth Lyons Jones

The number of recognizable patterns of malformation has more than tripled during the last 25 yr. The potential prenatal effect of various drugs, chemicals, and environmental agents is better appreciated, and the number of genetic and non-genetic defects in which prenatal detection is possible has increased. This chapter provides an approach to children with a prenatal onset of structural defects that is predicated on the concept that the

nature of the structural defects represents a clue to the time of onset, mechanism of injury, and possible etiology of the problem, all of which determine the necessary evaluation (Tables 97–1 and 97–2). This approach permits systematic narrowing of the diagnostic possibilities so that other sections of this textbook or one of the basic compendiums on dysmorphology can be used to make a specific diagnosis. The terminology of some malformations is noted in Table 97–3 .

Structural defects of prenatal onset can be separated into those that represent a single primary defect in development and those that represent a multiple malformation syndrome. In most cases of a single primary defect, the defect involves only a single structure, the child otherwise being completely normal. The seven most common single primary defects in development are congenital hip dislocation (Chapter 668.1), talipes equinovarus (Chapter 664.3), cleft lip with or without cleft palate (Chapter 291), cleft palate alone (Chapter 291), cardiac septal defects (Chapters 417 and 419), and defects in neural tube closure (Chapter 585). For most, the etiology is unknown, and counseling regarding the risk of recurrence is difficult. However, many of the more common single primary defects are explained on the basis of multifactorial inheritance (Chapter 69), which carries a recurrence risk of between 3% and 5% for the next child of unaffected parents with one affected child. The multifactorial threshold model was developed to explain the empirical 3–5% risk for recurrence in siblings for common single primary defects. Although this figure remains the basis for recurrence risk counseling, the model may not be completely accurate. As the genetic basis for common malformations is elucidated, genetic heterogeneity becomes apparent (Tables 97–4 and 97–5). For some defects, a few major genes rather than many genes may determine genetic susceptibility. For others, a monogenetic etiology may be apparent. For example, a study of the offspring of adults with major heart defects indicates that an

TABLE 97-1 -- Relative Timing and Developmental Pathology of Certain Malformations

Tissue	Malformation	Defect in	Causes Before	Comment
Central nervous system	Anencephaly	Closure of anterior neural tube	26 days	Subsequent degeneration of forebrain
	Meningomyelocele	Closure in a portion of the posterior neural tube	28 days	80% lumbosacral
Face	Cleft lip	Closure of lip	36 days	42% are associated with cleft palate
	Cleft maxillary palate	Fusion of maxillary palatal shelves	10 wk	
	Branchial sinus and/or cyst	Resolution of branchial cleft	8 wk	Preauricular and along the line anterior to the sternocleidomastoid muscle
Gut	Esophageal atresia plus tracheoesophageal fistula	Lateral septation of foregut into trachea and foregut	30 days	
	Rectal atresia with fistula	Lateral septation of cloaca into rectum and urogenital sinus	6 wk	
	Duodenal atresia	Recanalization of duodenum	7–8 wk	
	Malrotation of gut	Rotation of intestinal loop so that cecum lies to the right	10 wk	Associated incomplete or aberrant mesenteric attachments
	Omphalocele	Return of midgut from yolk sac to abdomen	10 wk	
	Meckel diverticulum	Obliteration of vitelline duct	10 wk	May contain gastric or pancreatic tissue

	Diaphragmatic hernia	Closure of pleuroperitoneal canal	6 wk	
Genitourinary system	Exstrophy of bladder	Migration of infraumbilical mesenchyme	30 days	Associated müllerian and wolffian duct defects
	Bicornuate uterus	Fusion of lower portion of müllerian ducts	10 wk	
	Hypospadias	Fusion of urethral folds (labia minora)	12 wk	
	Cryptorchidism	Descent of testicle into scrotum	7–9 mo	
Heart	Transposition of great vessels	Directional development of bulbus cordis septum	34 days	
	Ventricular septal defect	Closure of ventricular septum	6 wk	
	Patent ductus arteriosus	Closure of ductus arteriosus	9–10 mo	
Limb	Aplasia of radius	Genesis of radial bone	38 days	Often accompanied by other defects of radial side of distal end of limb
	Severe syndactyly	Separation of digital rays	6 wk	
Complex	Cyclopia, holoprosencephaly	Prechordal mesoderm development	23 days	Secondary defects of midface and forebrain

Modified from Jones KL (editor): Smith's Recognizable Patterns of Human Malformation, 5th ed. Philadelphia, WB Saunders, 1997. From Behrman RE, Kliegman (editors): Nelson's Essentials of Pediatrics, 4th ed. Philadelphia, WB Saunders, 2002.

atrioventricular septal defect is most likely a single gene defect whereas the tetralogy of Fallot is most likely a polygenic defect with a small number of interacting genes.

Transcription factor mutations are particularly prone to multiple malformations because they regulate gene expression in many different tissues (see Tables 97–4 and 97–5). Rubinstein-Taybi syndrome consists of multiple congenital anomalies and is due to a loss-of-function mutation in CBP (CREB-binding protein), a co-activator of many transcription factors in different tissues. Waardenburg syndrome type I, caused by mutations of the *PAX3* gene, affects neural crest–derived cells. PAX3 is expressed in the developing neural crest and is a tissue-specific transcription factor. Type III Waardenburg syndrome is due to mutations in *MITF* (microphthalmos-associated transcription factor), which is expressed in pigmented cells and may be dependent on transactivation by PAX3. *HOX* (homeotic selector) genes are another class of tissue-specific transcription factors that share a protein motif, the homeodomain, that permits binding to DNA. Homeodomain regions are also present in other transcription factors (e.g., PAX3, PAX6). *HOX* genes are regionalized in the embryo and help select the developmental fate of these cells; HOXA and HOXB act rostral caudally, and HOXA and HOXD act on the axes of the developing limbs. *HOXD13* mutations produce synpolydactyly in humans.

Proteins from one cell can affect the development of a nearby cell in a paracrine-like signal. Morphogens are proteins that affect adjacent cell development along a concentration gradient. The *Sonic hedgehog (SHH)* genes express morphogens involved in cell development of the central nervous system (CNS) and the limb buds. Dominantly inherited *SHH* mutations produce holoprosencephaly; even a 50% reduction in the gene product alters the protein gradient of this morphogen and produces CNS and midfacial anomalies. In some families, a modifier gene or genes may produce variable expressivity of the phenotype despite the

same gene mutation. Gene environment interactions may also play a role, such as enzymes that require a higher than normal amount of a cofactor such as folic acid.

The extent to which multifactorial inheritance contributes to the etiology of some of the less common single defects in development

TABLE 97-3 -- **Definitions of Common Clinical Signs**

Sign	Definition
Brachycephaly	A condition in which head shape is shortened from front to back along the sagittal plane; the skull is rounder than normal
Brachydactyly	A condition of having short digits
Brushfield spots	Speckled white rings about two thirds of the distance to the periphery of the iris of the eye
Camptodactyly	Permanent flexion of one or more fingers associated with missing inner phalangeal creases indicating lack of finger movement from before 8 wk gestation
Clinodactyly	A medial or lateral curving of the fingers and usually refers to incurving of the 5th finger
Hypoplastic nail	An unusually small nail on a digit
Low-set ears	This designation is made when the helix meets the cranium at a level below a horizontal plane that is an extension of a line through both inner canthi
Melia	A suffix meaning "limb" (e.g., amelia—missing limb; brachymelia—short limb)
Ocular hypertelorism	Increased distance between the pupils of the two eyes
Plagiocephaly	A condition in which head shape is asymmetric in the sagittal or coronal planes; can result from asymmetry in suture closure or from asymmetry of brain growth

Posterior parietal hair whorl	A single whorl occurs to the right or left of midline and within 2 cm anterior to the posterior fontanel in 95% of cases. The whorl represents the focal point from which the posterior scalp skin was under growth tension during brain growth between the 10th and 16th wk of fetal development. Aberrant position of the whorl reflects an early defect in brain development
Preaxial polydactyly	Extra finger or toe present on the medial side of the hand or foot
Postaxial polydactyly	Extra finger or toe present on the lateral side of the hand or foot
Prominent lateral palatine ridges	Relative overgrowth of the lateral palatine ridges secondary to a deficit of tongue thrust into the hard palate
Scaphocephaly	A condition in which the head is elongated from front to back in the sagittal plane; most normal skulls are scaphocephalic
Shawl scrotum	The scrotal skin joins around the superior aspect of the penis and represents a mild deficit in full migration of the labial-scrotal folds
Short palpebral fissures	Decreased horizontal distance of the eye based on measurement from the inner to the outer canthus
Syndactyly	Incomplete separation of the fingers. It most commonly occurs between the 3rd and 4th fingers and between the 2nd and 3rd toes
Synophrys	Eyebrows that meet in the midline
Telecanthus	Lateral displacement of the inner canthi. The inner canthal distance is increased, but the inner pupillary distance is normal
Widow's peak	V-shaped midline, downward projection of the scalp hair in the frontal region. It represents an upper forehead intersection of the bilateral fields of periocular hair growth suppression. It usually occurs because the fields are widely spaced, as in ocular hypertelorism

is unclear. The fact that single primary defects are etiologically heterogeneous implies that some have an environmental etiology and others result from dominantly or recessively inherited single altered genes. Craniosynostosis (Chapter 585.12) secondary to in utero constraint is an example of the

TABLE 97-4 -- **Examples of Human Developmental Abnormalities According to Primary Cause**

Condition	Clinical Findings	Genetics and Pathogenesis
Single Gene		
Aniridia	Reduced or absent iris; frequent retinal, lens, and/ or corneal abnormalities	Autosomal semidominant loss- of- function mutations in the paired- like transcription factor *PAX6*; also observed along with Wilms tumor and genitourinary abnormalities as part of the 11p13 WAGR deletion syndrome (Wilms tumor, aniridia, ambiguous genitalia)
Rubenstein- Taybi syndrome	Mental retardation, broad thumbs and toes, down-slanting palpebral fissures, hypoplastic maxilla, prominent nose, congenital heart disease	Heterozygosity for loss- of-function mutations in the autosomal gene encoding CREB- binding protein (CBP), a transcriptional co- activator for many different target genes
Waardenburg syndrome	Deafness, white forelock, pale and/ or asymmetric eye pigmentation. Cases caused by *PAX3* mutations have abnormally wide space between the inner eyelids and occasional upper limb defects	Autosomal semidominant loss- of- function mutations in one of two different genes: *PAX3*, which encodes a pairedlike transcription factor expressed in the neural tube and somites, or *MITF*, which encodes a bHLH transcription factor expressed in developing pigment cells
Synpolydactyly	Interphalangeal webbing and extra digits in the hands and feet	Semidominant gain- of-function mutation in *HOXD13*
Holoprosencephaly	Defective morphogenesis with bilateral cleavage of the forebrain and midface causes manifestations ranging from mild (single central incisor) to severe (microcephaly, cyclopia)	Approximately 10% of cases caused by heterozygosity for loss- of- function mutations in *SHH*, which encodes a dosage- sensitive paracrine signaling molecule; other etiologies include single- gene loci, multifactorial causes, and chromosomal imbalance syndromes
Cornelia de Lange syndrome	Growth and mental retardation, upper limb deficiencies, synophrys, depressed nasal bridge, anteverted nares, thin upper lip	Usually sporadic and probably new dominant mutation of unknown gene; rare sibling recurrence may be germline mosaicism
Multifactorial and/ or Teratogenic		

Cleft lip with or without cleft palate	Absence of midline tissue from the upper lip; may extend posteriorly to involve the hard and soft palate	Isolated occurrences usually polygenic and associated with recurrence risk of 3 – 5%; less frequently, associated findings suggest syndromic cause
Fetal alcohol syndrome	Microcephaly, optic nerve hypoplasia, developmental delay, facial abnormalities, hyperactive behavior	Prenatal exposure to ethanol during critical periods of brain development directly causes death of developing neurons
Retinoic acid embryopathy	Microtia (small ears), conotruncal cardiac malformations, posterior fossamalformations, thymus and parathyroid abnormalities	Exposure to isotretinoin causes abnormalities of neural crest – and branchial arch – derived structures
Chromosomal Imbalance		
Trisomy 21	Growth and mental retardation, abnormal facial features, hypotonia, endocardial cushion defect, duodenal atresia	50% increase in dosage for 250 genes on chromosome 21
Velocardiofacial syndrome	Cleft palate, prominent pear-shaped nose, conotruncal heart malformations, learning disabilities	Heterozygous microdeletion in 22q11 that contains 20 genes; individual genes responsible for morphogenetic abnormalities not yet identified

From Nussbaum RL, McInnes RR, Willard HF (editors): Thompson and Thompson Genetics in Medicine, 6th ed. Philadelphia, WB Saunders, 2001.

TABLE 97-5 -- Homologs of *Drosophila* Developmental Control Genes as Causes of Human Abnormalities

Condition	Gene	Clinical Findings
Nevoid basal cell carcinoma syndrome	*Drosophila patched* gene required for embryonic segmentation; human *PTC* gene is 29% similar	Overgrowth, skeletal abnormalities, increased susceptibility to basal cell carcinoma and medulloblastoma
Greig syndrome; Pallister-Hall syndrome; postaxial polydactyly	*Drosophila cubitus interruptus* gene required for embryonic segmentation; human *GLI3* gene is 22% identical	Extra digits (polydactyly), fusion of bony sutures in skull (craniosynostosis), hypothalamic tumors (in Pallister-Hall syndrome)
Holoprosencephaly (HPE3)	*Drosophila hedgehog* gene required for embryonic segmentation; human *SHH* gene is 38% identical	Reduced or absent development of forebrain and midline facial structures
Saethre-Chotzen syndrome	*Drosophila twist* gene required for mesoderm development; human *TWIST* gene is 32% similar	Craniosynostosis and abnormal facial features
Townes-Brock syndrome	*Drosophila spalt* gene required for specification of head and tail embryonic regions; human *SALL1* gene is 21% identical	Limb deficiency, ear abnormalities, anal atresia or stenosis

From Nussbaum RL, McInnes RR, Willard HF (editors): Thompson andThompson Genetics in Medicine, 6th ed. Philadelphia, WB Saunders, 2001.

former, whereas postaxial polydactyly (Chapter 671.7) illustrates the latter. Before multifactorial risk figures are used for counseling when a single primary defect is recognized, references should be consulted to determine whether other risk figures are available.

In contrast to the concept of the single primary defect in development, the designation *multiple malformation syndrome* is used when several observed structural defects all have the same known or presumed etiology. The defects usually include a number of anatomically unrelated errors in morphogenesis. Multiple malformation syndromes are caused by chromosomal abnormalities, by teratogens, and by single-gene defects inherited in mendelian patterns (see Table 97–4). Risks of recurrence range from zero, in cases that represent fresh gene mutations or are caused by teratogens, to 100%, in the case of a child with Down syndrome in which the mother is a balanced 21/21 translocation carrier (Chapter 70).

Single Primary Defects in Development.

These defects are subcategorized according to the nature of the error in morphogenesis that has produced the observed structural defect: malformation, deformation, disruption, or dysplasia of a developing structure. A *malformation* is a primary structural defect arising from a localized error in morphogenesis. A *deformation* is an alteration in shape or structure of a part that has differentiated normally. The term *disruption* is used for a structural defect resulting from destruction of a previously normally formed part. The term *dysplasia* refers to an abnormal

organization of cells and the structural consequences.

MALFORMATIONS.

Most children with a localized malformation, such as cardiac septal defects, are otherwise completely normal. After surgical correction, the prognosis is excellent. When neither dominant nor recessive inheritance is established, multifactorial recurrence risk factors (2–5%) apply to unaffected parents.

DEFORMATIONS.

Most deformations involve the musculoskeletal system and are probably caused by intrauterine molding. The pressure producing such molding may be intrinsic, the result of neuromuscular imbalance within the fetus, or extrinsic, secondary to fetal crowding. In either case, the impaired ability of the fetus to kick results in decreased fetal movement, an important factor in development of the normal musculoskeletal system, particularly with respect to normal joint development. In addition, marked positional deformation of any body part can occur when the fetus is unable to change position and thus alter the direction along which potentially deforming forces are being directed.

Intrinsically derived positional deformation of prenatal onset occurs in disorders involving muscle degeneration, such as the Steinert myotonic dystrophy syndrome, and disorders involving motor neurons, such as Werdnig-Hoffmann disease (Chapter 603.2). Early defects in development of the CNS are more common causes of positional deformations and should be seriously considered whenever a structural defect is thought to be intrinsically derived.

Fetal crowding, the most common cause of an extrinsically derived deformation of prenatal onset, is usually due to a decreased volume of amniotic fluid, a situation that occurs normally during the later weeks of gestation when the fetus is undergoing extremely rapid growth, and to the primigravid state. However, it also occurs abnormally with diminished fetal urinary output and chronic leakage of amniotic fluid.

Other extrinsic factors associated with the development of deformations include breech presentation and the shape of the amniotic cavity (Fig. 97–1). When a fetus is in the breech position, the legs may be trapped between the body and the uterine wall. The fetus is unable to kick optimally in this position, and the incidence of deformations is increased 10-fold. The shape of the amniotic cavity, which has a profound effect on the shape of the fetus that lies within it, is influenced by many factors, including uterine shape; volume of amniotic fluid; size and shape of the fetus; presence of more than one fetus; site of placental implantation; presence of uterine tumors; shape of the abdominal cavity, which is influenced by the pelvis, sacral promontory, and neighboring abdominal organs; and tightness of the abdominal musculature.

Various forms of talipes and congenital hip dislocation are the most frequently observed congenital postural deformities. Most children with these deformations are otherwise completely normal, and their prognosis is excellent. Correction usually occurs spontaneously. However, recognizing that a structural defect represents a deformation does not always imply "normal" fetal crowding and should lead to careful consideration of other etiologic possibilities that might have far greater significance to the child. For example, because decreased fetal movement can be secondary to serious neurologic abnormalities, multiple joint contractures should alert the physician to the possibility of a malformation in CNS development. Although congenital hip dislocations and talipes have a 3–5% recurrence risk, most deformations are the result of physiologic crowding and have a lower risk of recurrence. Deformations that are due to pathologic crowding (e.g., uterine tumors or malformation) have a much higher recurrence risk unless the factors leading to crowding are altered before subsequent pregnancies. Deformations that are the result of an underlying malformation (e.g., renal agenesis) have a recurrence risk similar to that of the underlying malformation.

DISRUPTION.

Disruption defects occur after destruction of a previously normally formed part. At least two basic mechanisms

Figure 97-1 Breech deformation sequence.

are known to produce disruption. One involves entanglement followed by tearing apart or amputation of a normally developed structure, usually a digit, arm, or leg, by strands of amnion floating within amniotic fluid (i.e., amniotic bands) (Fig. 97–2). The second involves interruption of the blood supply to a developing part, which leads to infarction, necrosis, and/or resorption of structures distal to the insult. If interruption of the blood supply occurs early in gestation, the disruptive defect that is seen at term usually involves atresia or absence of a particular part. If the infarction occurs later, necrosis is more likely to be present. Examples of disruptive single primary defects for which infarctive mechanisms have been implicated include non-duodenal intestinal atresia, gastroschisis (Chapter 83.2), porencephaly (Chapter 585), and terminal transverse limb reduction defects. The extent to which disruption of a developing structure plays a role in dysmorphogenesis is unknown.

Genetic factors play a minor role in the pathogenesis of disruptions; most are sporadic events in otherwise normal families. The prognosis for a disruptive defect is determined entirely by the extent and location of the tissue loss. Thus, a child with a limb amputation has an excellent prognosis for normal function, whereas a child with porencephaly does not.

DYSPLASIA.

Dysplasias may be localized or generalized. Localized dysplasias are usually single primary defects in development (e.g., hemangiomas). Localized dysplasia may be due to mosaic expression of a gene mutation occurring in the embryo, or it may be caused by agents (teratogens, viruses) that selectively injure susceptible cells (lens—rubella). However, generalized dysplasias, such as connective tissue disorders, are usually manifested as multiple malformation syndromes with involvement of a wide variety of structures because of the widespread distribution of

the dysplastic tissue.

The causes of the vast majority of localized dysplasias are unknown. Because many generalized dysplasias are the result of abnormal genes, it is possible that localized dysplasias will reflect

Figure 97-2 Amniotic band disruption sequence.

somatic mutation in specific tissues. The hypothesis is consistent with the observation that the empirical recurrence risk for localized dysplasias is low. The process of dysplasia appears to involve deregulation of growth; hence, most dysplasias change over time. Capillary hemangiomas become involuted, and bathing trunk nevi carry a risk of malignant transformation. Knowledge of the natural history of a lesion is critical in the long-term follow-up of children with localized dysplasias.

SEQUENCE.

The pattern of multiple anomalies that occurs when a single primary defect in early morphogenesis produces multiple abnormalities through a cascading process of secondary and tertiary errors in morphogenesis is called a sequence. When evaluating a child with multiple anomalies, the physician must differentiate between multiple anomalies secondary to a single localized error in morphogenesis (a sequence) and a multiple malformation syndrome. In the former, recurrence risk counseling for the multiple anomalies depends entirely on the risk of recurrence for the single localized malformation.

The terms *malformation*, *deformation*, and *disruption sequence* are used to describe only the initiating error in morphogenesis of a sequence if it is known. For example, the Robin malformation sequence (Chapter 292) is a pattern of multiple anomalies, all of which are produced by a single prenatal-onset defect in development—mandibular hypoplasia. Because the tongue is relatively small for the oral cavity, it drops back (glossoptosis), blocks closure of the posterior palatal shelves, and causes a U-shaped cleft palate. Recognizing that all the observed defects are due to a single localized error permits recurrence risk counseling based on the single defect.

The infant shown in Figure 97–1 has bathrocephaly, torticollis, facial asymmetry, a dislocated hip, and valgus anomalies of both feet as a result of compression of developing fetal parts. This pattern is the *breech deformation sequence*. Intrauterine crowding occurred because the large-sized infant was delivered in a breech position from a small, primigravida mother; recurrence risk is therefore negligible. Recognizing the deformational

nature of the abnormalities is helpful with respect to prognosis. All the problems should resolve spontaneously or with postural therapy.

In the *amniotic band disruption sequence,* all the craniofacial and limb defects are secondary to constrictions caused by entanglement in multiple fibrous strands of amnion extending from the placental insertion of the umbilical cord to the surface of the amnion-denuded chorion or floating freely within the chorionic sac (see Fig. 97–2). These strands of amnion, which result from disruption of the normally formed membrane, can cause secondary defects through several mechanisms. Malformations occur if a strand of amnion interferes with the normal sequence of development; for example, a strand of amnion may interrupt fusion of the facial processes so that a cleft lip results. Disruptions occur secondary to tearing apart of structures that have previously developed normally; for example, an amniotic band might cleave areas in the developing craniofacies along lines not conforming to the normal planes of facial closure.

Deformations caused by fetal compression occur secondary to *oligohydramnios* or *tethering of a fetal part*. The former may result from rupture of both amnion and chorion and subsequent chronic leakage of amniotic fluid. Tethering occurs when the fetus or one of its parts becomes immobilized by the constraining effect of an amniotic band so that it is unable to change position and thus alter the direction along which potentially deforming forces are being directed. The recurrence risk is based on the recurrence risk for amnion rupture; unaffected parents have not been reported to give birth to more than one child affected with this disorder.

Multiple Malformation Syndromes.

This category includes patients in whom one or more developmental anomalies of two or more systems have occurred, all of which are thought to be due to a common etiology. Other than Down syndrome, with an incidence of 1/660, and XXY syndromes (1/500 males), none of these disorders occurs more frequently than 1/3,000 live births.

Multiple malformation syndromes may be caused by chromosomal and genetic abnormalities and by teratogens. A number of them are associated with chromosome abnormalities (Chapter 70).

Disorders that are due to single mutant genes (dominant or X-linked in males) or to pairs of mutant genes (autosomal recessive) also cause a number of recognizable multiple malformation syndromes of prenatal onset. Correct diagnosis depends on clinical recognition because in most cases, no laboratory test is able to confirm the diagnosis. A family history of a similarly affected individual is extremely helpful. However, in many patients with multiple malformation syndromes of genetic etiology, the occurrence is sporadic and thus represents fresh gene mutations. In such situations, all family members are normal, and the diagnosis depends entirely on evaluation of the patient's phenotype. It is important to recognize that variability in expression is the rule in autosomal dominant conditions. The branchio-oto-renal syndrome is an autosomal dominant condition associated with hearing loss, preauricular pits, branchial fistulas or cysts, anomalous pinnae with a malformed middle and/or inner ear, lacrimal duct stenosis/aplasia, and renal dysplasia. In some cases, the parent of a severely affected child could have a preauricular pit as the only manifestation of the altered gene, thus highlighting the importance of a careful physical examination of both parents before providing counseling on the risk of

recurrence.

Disorders caused by teratogens include multiple malformation syndromes resulting from the effect of specific infections or pharmacologic or chemical agents with which the embryo or fetus has come in contact during gestation. An example is retinoic acid embryopathy (isotretinoin [Accutane] embryopathy), which is associated with craniofacial anomalies, particularly microtia and/or anotia; cardiovascular defects; CNS anomalies; thymic abnormalities; and a subnormal range of intelligence. The offspring of women who take isotretinoin between 15 days after conception and the end of the 1st trimester have a 35% risk for this disorder. Such conditions may be prevented before conception, particularly in the case of drugs and chemicals, if the mother is aware that the agent in question can affect her baby. It is difficult, on the other hand, for a pregnant woman to avoid contact with all infectious agents.

A careful history of drug intake (Chapter 85.4) and chemical exposure (Chapter 701) should be obtained from the parents of all children with multiple malformation syndromes, especially when the etiology of the disorder is unknown. *A Catalog of Teratogenic Agents,* by T.H. Shepard, and *Drugs in Pregnancy and Lactation,* by Briggs, Freeman, and Yaffe, as well as on-line references such as REPROTOX and TERIS are excellent references for determining whether the agent that the mother has been exposed to is a known teratogen.

Specific and easily distinguishable phenotypes do not exist for each of the infectious diseases commonly associated with altered fetal development, but intrauterine infection can frequently be suspected in those with an overall pattern of malformation (Chapter 98). An intrauterine infection should be considered if the infant is small for gestational age or developmentally delayed; in addition, the infant may be affected by microcephaly or hydrocephalus; by ocular defects, including microphthalmos, chorioretinitis, cataracts, or glaucoma; and by hepatosplenomegaly and thrombocytopenia. Intrauterine infections have a wide spectrum of clinical manifestations, from a severely affected newborn with multiple malformations to a child with no malformations who has learning disabilities that are first identified at school age.

In addition, some well-recognized multiple malformation syndromes occur in which virtually all cases have been sporadic in otherwise normal families. Examples include the Costello syndrome, a disorder associated with postnatal growth deficiency, mental retardation, macrocephaly, a coarse face, loose skin, hyperkeratotic palms and soles, papillomas in the perioral, nasal, and anal regions, cardiomyopathy, and cerebral atrophy; and the Kabuki syndrome, characterized by postnatal growth deficiency, mental retardation, long palpebral fissures, protuberant ears, preauricular pits, cardiac defects, and prominent fingertip pads. Although the etiology of these two disorders is unknown, it is now possible through molecular techniques to determine the etiology of many of them. For example, studies using fluorescent in situ hybridization indicate that the *Williams syndrome* is due to a deletion of one elastin allele located within chromosome subunit 7q11.23, whereas the *Rubinstein-Taybi syndrome* is due to a microdeletion in 16p13.3 (see Chapter 70). For *Prader-Willi syndrome*, another common sporadic disorder, the presence of the phenotype is dependent on whether the gene has been inherited from the mother or the father, a mechanism known as genetic imprinting. More than 50% of children with Prader-Willi syndrome have a chromosomal deletion involving band q11.2 of the long arm of chromosome 15. In all cases, the deleted chromosome is paternally derived (see Chapters 69 and 70). Although the gene for *Brachmann-de Lange syndrome* has not been localized, most cases are believed to be due to a single gene transmitted in autosomal dominant fashion. The low recurrence risk most likely represents the inability of more severely affected individuals to reproduce. Experience with many children with each of these disorders has provided a vast amount of information that can be extremely

helpful to parents in understanding their child's behavior and to educators in planning an appropriate curriculum. For example, a specific behavioral phenotype has been delineated for the de Lange syndrome; the parents' awareness that the child's aberrant behavior is “normal” for the de Lange syndrome rather than being “their fault” can be extremely helpful in relieving their anxiety and guilt. For the *Williams syndrome*, a different, but equally characteristic behavioral phenotype has been documented and includes the following: multiple developmental motor disabilities affecting strength, balance, coordination, and motor planning; sensory integration dysfunction relating primarily to hypersensitivity to sound; hyperactivity; delayed expressive and receptive language skills with simultaneous age-appropriate grammar and articulation; better reading than mathematics ability; and cognitive dysfunction ranging from learning disabilities to mental retardation. This knowledge of a child's particular strengths and weaknesses may allow educators to develop a curriculum that will give affected children a better chance to reach their potential.

In certain nonrandom associations of malformations, it has not been determined whether the pattern is a sequence or a syndrome. Such related malformations are designated **associations**. One important clinical example is the *VATER association*, which includes vertebral defects, anal atresia, tracheoesophageal fistula with atresia, radial upper limb hypoplasia, and renal defects. A single umbilical artery and cardiac and genital anomalies are also seen in this association. These defects are likely to occur together in almost any combination of two or more and usually represent a sporadic occurrence in an otherwise normal family.

The ultimate goal in evaluating a child with structural defects is making a specific overall diagnosis. When such a diagnosis is made, appropriate recurrence risk counseling for the parents, accurate prognostication about the child's future development, and an appropriate plan for achievement of the child's potential are usually possible (see Chapter 37). When an overall diagnosis is lacking, the most that can be expected is a better understanding of the nature and onset of the problem, which may often be helpful to parents and others dealing with the child.

Section 2 - *Infections of the Neonatal Infant*

Barbara. J. Stoll *

Chapter 98 - Pathogenesis and Epidemiology

Infections are a frequent and important cause of morbidity and mortality in the neonatal period. As many as 2% of fetuses are infected in utero, and up to 10% of infants have infections in the 1st mo of life. Neonatal infections are unique for several reasons. (1) Infectious agents can be transmitted from the mother to the fetus or newborn infant by diverse modes. (2) Newborn infants are less capable of responding to infection because of one or more immunologic deficiencies. (3) Coexisting conditions often complicate the diagnosis and management of neonatal infections. (4) The clinical manifestations of newborn infections vary and include subclinical infection, mild to severe manifestations of focal or systemic infection, and rarely, congenital malformations resulting from infection in the 1st trimester. The timing of exposure, inoculum size, immune status, and virulence of the etiologic agent influence the expression of disease in a fetus or newborn infant. (5) Maternal infection that is the source of transplacental fetal infection is often undiagnosed during pregnancy because the mother was either asymptomatic or had nonspecific signs and symptoms at the time of acute infection. (6) A wide variety of etiologic agents infect the newborn, including bacteria, viruses, fungi, protozoa, and mycoplasmas. (7) Finally, with advances in neonatal intensive care, increasingly immature, very low birthweight (VLBW) newborns are surviving and remain in the hospital for a longer time, an environment that puts them at ongoing high risk for infection.

98.1 Modes of Transmission and Pathogenesis

Pathogenesis of Intrauterine Infection.

Intrauterine infection is a result of clinical or subclinical maternal infection with a variety of agents (e.g., cytomegalovirus [CMV], *Treponema pallidum*, *Toxoplasma gondii*, rubella virus, varicella virus, parvovirus B19) and hematogenous transplanscental transmission to the fetus. Transplacental infection may occur at any time during gestation, and signs and symptoms may be present at birth or be delayed

* Updated and edited from the 16th Edition section by Dr. Sam Gotoff.

for months or years (Fig. 98–1). Infection may result in early spontaneous abortion, congenital malformation, intrauterine growth restriction, premature birth, stillbirth, acute disease in the neonatal period, or asymptomatic persistent infection with sequelae later in life. In some cases, no apparent effects are seen in the newborn infant.

The timing of infection during gestation affects the outcome. First trimester infection may alter embryogenesis, with resulting congenital malformations (congenital rubella). Third trimester infection often results in active infection at the time of delivery (toxoplasmosis, syphilis). Infections that occur late in gestation may lead to a delay in clinical manifestations until some time after birth (syphilis).

Maternal infection is a necessary prerequisite for transplacental infection. For some etiologic agents, maternal immunity is effective and antibody is protective for the fetus (rubella). For other agents, maternal antibody may ameliorate the outcome of infection or have no effect (CMV). Even without maternal antibody, transplacental transmission of infection to a fetus is variable, and the placenta often functions as an effective barrier.

Pathogenesis of Ascending Bacterial Infection.

In most cases, the fetus or neonate is not exposed to potentially pathogenic bacteria until the membranes rupture and the infant passes through the birth canal and/or enters the extrauterine environment. The human birth canal is colonized with aerobic and anaerobic organisms that may result in ascending amniotic infection and/or colonization of the neonate at birth. Vertical transmission of bacterial agents that infect the amniotic fluid and/or vaginal canal may occur in utero or more commonly during labor and/or delivery (Fig. 98–2). Chorioamnionitis results from microbial invasion of amniotic fluid, usually as a result of prolonged rupture of the chorioamniotic membrane. On occasion,

Figure 98.1-1 Pathogenesis of ematogenous transplacental infections. (From Klein JO, Remington JS: Current concepts of infections of the fetus and newborn infant. In Remington JS, Klein JO [editors]: *Infectious Diseases of the Fetus and Newborn Infant*, 5th ed. WB Saunders, Philadelphia, 2002, pp 1–23.).

amniotic infection occurs with apparently intact membranes or with a relatively brief duration of membrane rupture. Amniotic fluid infection may be asymptomatic or may produce maternal fever, with or without local or systemic signs of chorioamnionitis. The duration of membrane rupture is directly correlated with the development of chorioamnionitis. Previously, longer than 24?hr was considered prolonged rupture of membranes because microscopic evidence of inflammation of the membranes is uniformly present when the duration of rupture exceeds 24?hr. However, at 18?hr of membrane rupture, the incidence of early-onset disease with group B streptococcus (GBS) increases significantly. Therefore, longer than 18?hr is the current cutoff for increased risk of neonatal infection. Difficult or traumatic delivery and premature

delivery are also associated with an increased frequency of neonatal infection.

In most cases, bacterial colonization does not result in disease. Factors influencing which colonized infant will develop disease are not well understood but include prematurity, underlying illness, invasive procedures, inoculum size, virulence of the infecting organism, and transplacental maternal antibodies (Fig. 98–3). Aspiration or ingestion of bacteria in amniotic fluid may lead to congenital pneumonia or systemic infection, with manifestations becoming apparent before delivery (fetal distress, tachycardia), at delivery (perinatal asphyxia), or after a latent period of a few hours (respiratory distress, shock). Aspiration or ingestion of bacteria during the birth process may lead to infection after an interval of 1–2 days.

Resuscitation at birth, particularly if it involves endotracheal intubation, insertion of an umbilical vessel catheter, or both, is associated with an increased risk of bacterial infection. Explanations include the presence of infection at the time of birth or acquisition of infection during the invasive procedures associated with resuscitation.

Figure 98.1-2 Pathways of ascending or intrapartum infection..

Pathogenesis of Late-Onset Postnatal Infections.

After birth, neonates are exposed to infectious agents in the nursery or in the community. Postnatal infections may be transmitted by direct contact with hospital personnel, the mother, or other family members; from breast milk (HIV, CMV); or from inanimate sources such as contaminated equipment. The most common source of postnatal infections in hospitalized newborns is hand contamination of health care personnel.

Most cases of meningitis result from hematogenous dissemination. Less often, meningitis results from contiguous spread as a result of contamination of open neural tube defects, congenital sinus tracts, or penetrating wounds from fetal scalp sampling or internal fetal electrocardiographic monitors. Abscess formation,

Figure 98.1-3 Factors influencing the balance between health and disease in neonates exposed to a potential pathogen. ROM = rupture of membranes. (Adapted from Baker CJ: Group B streptococcal infections. *Clin Perinatol* 1997;24:59.).

ventriculitis, septic infarcts, hydrocephalus, and subdural effusions are complications of meningitis that occur more often in newborn infants than in older children.

98.2 Immunity

Diminished concentrations of immunoglobulins and other immunologic factors and decreased function of neutrophils and other cells involved in the response to infection have been demonstrated in both term and preterm infants. Despite these alterations in immune function, the rate of systemic infection in newborns is low in the absence of obstetric and neonatal risk factors. All newborns enter an unsterile environment, but infection develops in only a few. The immunologic system is discussed in detail in Part XIII.

Immunoglobulins.

IgG is actively transported across the placenta, with concentrations in a full-term infant comparable to those in the mother. The specificity of IgG antibody in cord blood is dependent on the mother's previous antigenic exposure and immunologic response. In premature infants, cord IgG levels are directly proportional to gestational age. Studies of type-specific IgG antibodies to GBS have shown that the ratio of cord to maternal serum concentrations is 1.0, 0.5, and 0.3 at term, 32 wk, and 28 wk of gestation, respectively. Levels of maternally derived IgG fall rapidly after birth. Infants with birthweights less than 1,500?g become significantly hypogammaglobulinemic, with mean plasma IgG concentrations in the range of 200–300?mg/dL in the 1st wk of life. Other classes of immunoglobulins are not transferred across the placenta, although a fetus can synthesize IgA and IgM in response to intrauterine infection.

The presence of passively transferred specific IgG antibody in adequate concentration provides neonates protection against infections to which protection is mediated by antibody (e.g., tetanus, encapsulated bacteria such as GBS). Specific bactericidal and opsonic antibodies against enteric gram-negative bacteria are predominantly in the IgM class. In general, newborn

---

infants lack antibody-mediated protection against *Escherichia coli* and other Enterobacteriaceae.

Complement.

The complement system mediates bactericidal activity against certain organisms such as *E. coli* and functions as an opsonin with antibody in the phagocytosis of bacteria such as GBS. Essentially no transplacental passage of complement from the maternal circulation takes place. A fetus begins to synthesize complement components as early as the 1st trimester. Full-term newborn infants have slightly diminished classical pathway complement activity and moderately diminished alternative pathway activity. Considerable variability, however, is seen in both the concentration and activity of complement components. Premature infants have lower levels of complement components and less complement activity than full-term newborns do. These deficiencies contribute to diminished complement-derived chemotactic activity and to a diminished ability to opsonize certain organisms in the absence of antibody. Many studies have been performed with different strains of microorganisms and under different conditions and have examined both the classical and alternative pathways. In general, opsonization of *Staphylococcus aureus* is normal in neonatal sera, but various degrees of impairment have been noted with

GBS and *E. coli*.

Neutrophils.

Quantitative and qualitative deficiencies of the phagocyte system are important factors contributing to newborns' increased susceptibility to infection. Neutrophil migration (chemotaxis) is abnormal at birth in both term and preterm infants. In addition, neonatal neutrophils have decreased adhesion, aggregation, and deformability, all of which may delay the response to infection. Abnormal expression of cell membrane adhesion molecules (the $ß_2$ integrins and selectins) and abnormalities in the neonatal neutrophil cytoskeleton contribute to abnormal chemotaxis. With adequate opsonization, phagocytosis and killing by neutrophils are comparable in newborn infants and adults. However, in the face of infectious or noninfectious stress (respiratory distress syndrome [RDS]), the ability of neonatal neutrophils to phagocytose gram-negative (but not gram-positive) bacteria appears to be decreased. The oxidative respiratory burst of neonatal neutrophils is impaired and is a factor in the increased risk of sepsis, especially in preterm infants.

The number of circulating neutrophils is elevated after birth in both term and preterm infants, with a peak at 12?hr that returns to normal by 22?hr. Band neutrophils constitute less than 15% in normal newborns and may increase in newborns with infection and other stress responses such as asphyxia.

Neutropenia is frequently observed in preterm infants and those with intrauterine growth restriction, and it increases the risk for sepsis. The neutrophil storage pool in newborn infants is 20–30% of that in adults and is more likely to be depleted in the face of infection. Mortality is increased when sepsis is associated with severe sepsis-induced neutropenia and bone marrow depletion. Granulocyte colony–stimulating factor (G-CSF) and granulocyte-macrophage colony–stimulating factor (GM-CSF) are cytokines that play important roles in the proliferation, differentiation, functional activation, and survival of phagocytes. These cytokines stimulate myeloid progenitor cells, increase the bone marrow neutrophil storage pool, induce peripheral blood neutrophilia, and influence neutrophil function, including enhancement of bactericidal activity. Although these myeloid colony–stimulating factors influence neutrophil number and function, their clinical utility in the treatment and/or prevention of neonatal sepsis remains undetermined.

Monocyte-Macrophage System.

The monocyte-macrophage system consists of circulating monocytes and tissue macrophages, particularly in the liver, spleen, and lung. Activated macrophages are involved in antigen presentation, phagocytosis, and immune modulation. The number of circulating monocytes in neonatal blood is normal, but the mass or function of macrophages in the reticuloendothelial system is diminished in newborns, particularly in preterm infants. In both term and preterm infants, chemotaxis of monocytes is impaired; this impairment affects the inflammatory response in tissues and the results of delayed hypersensitivity skin tests. However, monocytes from neonates ingest and kill microorganisms as well as monocytes from adults do.

Natural Killer Cells.

Natural killer (NK) cells are a subgroup of lymphocytes that are cytolytic against cells infected with viruses. NK cells also lyse cells coated with antibody in a process called antibody-dependent cell-mediated cytotoxicity (ADCC). NK cells appear early in gestation and are present in cord blood in numbers equivalent to those in adults; however; neonatal NK cells have decreased cytotoxic activity and ADCC in comparison to adult cells. The diminished cytotoxicity against herpes simplex virus (HSV)-infected cells may predispose to disseminated HSV infection in newborns (see Chapter 231).

Cytokines/Inflammatory Mediators.

The patient's response to infection and clinical outcome involve a balance between pro-inflammatory and anti-inflammatory cytokines. Several adverse neonatal outcomes, including brain injury, necrotizing enterocolitis, and bronchopulmonary dysplasia (BPD), may be mediated by the cytokine response to infection in the mother, fetus, or newborn. The list of mediators that have been studied in newborns is long and includes tumor necrosis factor-a (TNFa), interleukin 1 (IL-1), IL-4, IL-6, IL-8, IL-10, IL-12, platelet-activating factor, and the leukotrienes. The release of various inflammatory mediators in response to infection offers the potential opportunity to facilitate an early diagnosis of infection. Studies of potential surrogate markers for neonatal infection have focused on the association of bacterial sepsis, pneumonia, and necrotizing enterocolitis with elevated cytokine levels. TNFa, IL-6, and IL-8 are elevated in neonates with sepsis.

Innate immunity involves nonspecific cellular and humoral responses to an infectious agent without previous exposure. Neutrophil granules contain many enzymes; one protein, bactericidal/permeability-increasing protein (BPI), binds to the endotoxin in the cell wall of gram-negative bacteria. It facilitates opsonization and prevents the inflammatory response to endotoxin. BPI activity may also be decreased in neonates.

98.3 Etiology of Fetal and Neonatal Infection

A number of agents may infect newborns in utero, intrapartum, or postpartum (Table 98–1 and Box 98–1). Intrauterine transplacental infections of significance to the fetus and/or newborn include syphilis, rubella, CMV, toxoplasmosis, parvovirus B19, and varicella. Although HSV, HIV, hepatitis B virus (HBV), hepatitis C virus, and tuberculosis (TB) can each result in transplacental infection, the most common mode of transmission for these agents is intrapartum during labor and delivery with passage through an infected birth canal (HIV, HSV, HBV) or postnatal from contact with an infected mother or caretaker (TB).

Any microorganism inhabiting the genitourinary or lower gastrointestinal tract may cause intrapartum and postpartum infection. The most common bacteria are GBS, enteric organisms, gonococci, and chlamydiae. The more common viruses are CMV, HSV, and HIV.

Agents that commonly cause nosocomial infection are coagulase-negative staphylococci, gram-negative bacilli *(E. coli, Klebsiella pneumoniae, Salmonella, Enterobacter, Citrobacter, Pseudomonas aeruginosa, Serratia)*, enterococci, *S.*

aureus, and *Candida*. Viruses contributing to nosocomial neonatal infection include enteroviruses, CMV, hepatitis A, adenoviruses, influenza, respiratory syncytial virus, rhinovirus, parainfluenza, HSV, and rotavirus. Community-acquired pathogens such as *Streptococcus pneumoniae* may also cause infection in newborn infants after discharge from the hospital.

+ = relative frequency.

* Clostridium tetani *in some developing countries.*

Congenital pneumonia may be caused by CMV, rubella virus, and *T. pallidum* and less commonly by the other agents producing transplacental infection (Table 98–2). Microorganisms causing pneumonia acquired during labor and delivery include GBS, gram-negative enteric aerobes, *Listeria monocytogenes*, genital *Mycoplasma, Chlamydia trachomatis*, CMV, HSV, and *Candida* species.

The bacteria responsible for most cases of nosocomial pneumonia typically include staphylococcal species, gram-negative enteric aerobes, and occasionally, *Pseudomonas*. Fungi are responsible for an increasing number of systemic infections acquired during prolonged hospitalization of neonates. Finally, respiratory viruses cause isolated cases and outbreaks of nosocomial pneumonia. These viruses, usually endemic during the winter months and acquired from infected hospital staff or visitors to the nursery, include respiratory syncytial virus, parainfluenza virus, influenza viruses, and adenovirus. Respiratory viruses are the single most important cause of community-acquired pneumonia and are usually contracted from infected household contacts.

Box 98.3-1. Nonbacterial Causes of Systemic Neonatal Infections

VIRUSES

- Adenovirus
- Cytomegalovirus
- Enteroviruses
- Herpes simplex virus
- HIV
- Parvovirus
- Rubella virus
- Varicella-zoster virus

MYCOPLASMA

- *M. hominis*
- *Ureaplasma urealyticum*

FUNGI

- *Candida* species
- *Malassezia* species

PROTOZA

- Plasmodia
- *Toxoplasma gondii*
- *Trypanosoma cruzi*

TABLE 98.3-2 -- **Etiologic Agents of Neonatal Pneumonia According to Timing of Acquisition**

Transplacental	Perinatal	Postnatal
Cytomegalovirus	Anaerobic bacteria	Adenovirus
Herpes simplex virus	*Chlamydia*	* Candida species
Mycobacterium tuberculosis	Cytomegalovirus	Coagulase-negative staphylococci
Rubella virus	Enteric bacteria	Cytomegalovirus
Treponema pallidum	Group B streptococci	Echoviruses
Varicella-zoster virus	*Haemophilus influenzae*	* Enteric bacteria
	Herpes simplex virus	Influenza viruses A, B
	Listeria monocytogenes	Parainfluenza
	Mycoplasma	* Pseudomonas
		Respiratory syncytial virus
		Staphylococcus aureus

* *More likely in infants undergoing mechanical ventilation, with indwelling catheters, or after abdominal surgery.*

The most common bacterial causes of neonatal meningitis are GBS, *E. coli,* and *L. monocytogenes. S. pneumoniae*, other streptococci, non-typable *Haemophilus influenzae*, both coagulase-positive and coagulase-negative staphylococci, *Klebsiella, Enterobacter, Pseudomonas, T. pallidum*, and *Mycobacterium tuberculosis* may also produce meningitis. *Citrobacter diversus* is an important cause of brain abscess.

98.4 Epidemiology of Early- and Late-Onset Neonatal Infections

The terms early-onset and late-onset infection refer to the age at onset of infection in the neonatal period (Table 98–3). Originally divided arbitrarily as infections occurring before and after 1 wk of

TABLE 98.4-3 -- **Neonatal Infection by Age of Onset**

Characteristics	Early Onset	Late Onset	Late, Late Onset

Age at onset	Birth to 7 days usually <72 hr	7 to 30 days	>30 days
Maternal obstetric complications	Common	Uncommon	Varies
Prematurity	Frequent	Varies	Usual
Organism source	Maternal genital tract	Maternal genital tract/environment	Environment/community
Manifestation	Multisystem	Multisystem or focal	Multisystem or focal
Site	Normal nursery, NICU, community	NICU, community	NICU, community
NICU = neonatal intensive care unit.			

life, it is more useful to separate early- and late-onset infections according to peripartum pathogenesis. Early-onset infections are acquired before or during delivery. Late-onset infections are acquired after delivery in the normal newborn nursery, neonatal intensive care unit (NICU), or the community. The age at onset depends on the timing of vertical transmission and the virulence of the infecting organism. Pyogenic infections such as GBS are usually clinically apparent within the 1st 24?hr of life. Late, late-onset infections (occurring after 1 mo of life) have been reported, particularly in VLBW preterm infants.

The *incidence of neonatal bacterial sepsis* varies from 1–4 cases per 1,000 live births in developed countries, with considerable fluctuation over time and with geographic location. Term male infants have an approximately twofold higher incidence of sepsis than term females do. This sex difference is less clear in preterm low-birthweight (LBW) infants. Attack rates of neonatal sepsis increase significantly in LBW infants in the presence of maternal chorioamnionitis, congenital immune defects, asplenia, galactosemia *(E. coli)*, and malformations leading to high inocula of bacteria (obstructive uropathy).

Intrapartum antibiotics are used to reduce vertical transmission of GBS, as well as lessen neonatal morbidity after preterm rupture of membranes. After the introduction of selective intrapartum antibiotic prophylaxis to prevent perinatal transmission of GBS, rates of early-onset neonatal GBS infection in the United States declined from 1.7 cases per 1,000 live births to 0.6 per 1,000. Intrapartum chemoprophylaxis has had no effect on rates of late-onset GBS disease. Although some studies have reported a decline in non-GBS pathogens, as well as in GBS, others have reported no change in rates of non-GBS pathogens. Of concern are reports of an increase in gram-negative infections (especially *E. coli*) in VLBW infants in the face of a reduction in GBS sepsis.

The *incidence of meningitis* in newborn infants is 0.2–0.4 cases per 1,000 live births and is higher in preterm infants. Bacterial meningitis may be associated with sepsis or may occur as a focal infection. Meningitis currently develops in less than 20% of newborn infants with early-onset invasive bacterial infections.

Prematurity.

The most important neonatal factor predisposing to infection is prematurity or LBW. Preterm infants have a 3- to 10-fold higher incidence of infection than full-term, normal-birthweight infants do. A number of possible explanations have been proposed for the increased incidence of infection in preterm infants. (1) Maternal genital tract infection is considered to be an important cause of preterm labor, with an increased risk of vertical transmission to the newborn (Figs. 98–4 and 98–5 (Figure Not Available)). (2) The frequency of intra-amniotic infection is inversely related to gestational age. (3) Premature infants have documented immune dysfunction. (4) Premature infants often require prolonged intravenous access, endotracheal intubation, or other invasive procedures that provide a portal of entry or impair clearance mechanisms.

Figure 98.4-4 Potential pathways from choriodecidual bacterial colonization to preterm delivery. (From Goldenberg RL, Hauth JC, Andrews WW: Mechanisms of disease: Intrauterine infection and preterm delivery. *N Engl J Med* 2000;342:1500.)

Figure 98.4-5 (Figure Not Available) Potential sites of bacterial infection within the uterus. (From Goldenberg RL, Hauth JC, Andrews WW: Mechanisms of disease: Intrauterine infection and preterm delivery. *N Engl J Med* 2000;342:1500. Copyright 2000 Massachusetts Medical Society.)

Chorioamnionitis.

Attack rates of neonatal infection increase significantly in the presence of chorioamnionitis, which is diagnosed by amniotic fluid analysis or histologically. Clinical signs of chorioamnionitis include intrapartum fever (>38°C), maternal leukocytosis (white blood cell [WBC] count >18,000), and uterine tenderness. Rates of histologic chorioamnionitis are inversely related to gestational age and directly related to the duration of membrane rupture.

Nosocomial Infections.

Nosocomial, or hospital-acquired, infections are responsible for significant morbidity and late mortality in hospitalized newborns. Neonatal nosocomial infection is not uniformly defined. Many define nosocomial infections as infections occurring after 3 days of life that are not directly acquired from the mother's genital tract. The Centers for Disease Control and Prevention (CDC) defines a nosocomial infection as any infection occurring after admission to the NICU that was not transplacentally acquired. Rates of nosocomial infection in healthy term infants who are either rooming in with their mothers or staying in the well baby nursery are low (less than 1%). The majority of nosocomial infections occur in preterm or term infants who require special care. Risk factors for nosocomial infection in these infants include prematurity, LBW, invasive procedures, indwelling vascular catheters, parenteral

nutrition with lipid emulsions, endotracheal tubes, ventricular shunts, alterations in the skin and/or mucous membrane barriers, frequent use of broad-spectrum antibiotics, and prolonged hospital stay. Most nosocomial infections are bloodstream infections associated with an intravascular device. Other serious infections are pneumonia, meningitis, omphalitis, and necrotizing enterocolitis.

Large cohort studies of VLBW infants (under 1500?g birthweight) have reported nosocomial infection rates of 20–25%. Rates increase with decreasing gestational age and birthweight. The National Institute of Child Health and Human Development (NICHD) Neonatal Research Network has reported rates of 43% for infants 401–750?g, 28% for those 751–1000?g, 15% for those 1001–1250?g, and 7% for those 1251–1500?g. The National Nosocomial Infection Surveillance System (NNISS) monitors device-associated nosocomial infection rates. Rates are inversely related to birthweight and range from 11.4 infections/1,000 device days for infants under 1,000?g to 3.8 infections/1,000 device days for those over 2500?g. The widespread differences in practice regarding the inclusion of lumbar puncture in the diagnostic evaluation of an infant with suspected sepsis make it more difficult to determine rates of late-onset meningitis.

Various bacterial and fungal agents colonize hospitalized infants, health care workers, and visitors. Pathogenic agents can be transmitted by direct contact or indirectly via contaminated equipment, intravenous fluids, medications, blood products, or enteral feedings. Colonization of the infant's skin, umbilicus, and respiratory or gastrointestinal tract with pathogenic agents

often precedes the development of infection. Antibiotic use interferes with colonization by normal flora, thereby facilitating colonization with more virulent pathogens.

Multiple studies have reported that coagulase-negative staphylococci are the most frequent neonatal nosocomial pathogens. Among a cohort of 6,215 VLBW infants in the NICHD Neonatal Research Network, gram-positive agents were associated with 70%, gram-negative with 18%, and fungi with 12% of cases of late-onset sepsis (Table 98–4). Coagulase-negative staphylococcus, the single most common organism, was isolated in 48% of these infections. The emergence of nosocomial bacterial pathogens resistant to multiple antibiotics is a growing concern. Among NICU patients, methicillin-resistant *S. aureus*, vancomycin-resistant enterococci, and multidrug-resistant gram-negative pathogens are particularly alarming.

Viral organisms may also cause nosocomial infection in the NICU and include respiratory syncytial virus, varicella, influenza, rotavirus, and enteroviruses. For viral as well as bacterial agents, nursery outbreaks may occur in addition to individual cases. Hospital infection control policies are essential to prevent and/or contain nursery outbreaks.

The mean age at onset of the 1st episode of late-onset nosocomial sepsis is 2–3 wk, independent of the infecting pathogen. Nosocomial infections increase the risk of adverse outcomes, including prolonged hospitalization and mortality.

Active surveillance for nosocomial infection is essential to monitor overall rates of infection, rates of infection with specific pathogens, and antibiotic susceptibility patterns and to identify clusters of cases or true infectious outbreaks. Surveillance is based on the ongoing review of nursery infections and data from the microbiology laboratory; routine surveillance to detect colonization is not indicated. Culture results should indicate the bacterial isolate and the antimicrobial sensitivity pattern. Assessment of other microbial markers (biotype, serotype, DNA fingerprint) may be helpful in epidemics. During epidemics, investigation of possible reservoirs of infection, modes of transmission,

* *Patients with dual infections and patients excluded. According to the definitions in text, 276 (44%) CONS were definite infections and 353 (56%) were possible infections.*

and risk factors is necessary. Identification of colonized infants and nursery personnel may be helpful.

Infections acquired after discharge from the nursery are usually community acquired. They have the same epidemiologic considerations as other community-acquired infections in infants and children, except for protection provided by maternal antibody.

98.5 Clinical Manifestations of Transplacental Intrauterine Infections

Infection with agents that cross the placenta (CMV, *T. pallidum*, *T. gondii*, rubella, parvovirus B19, others) may be asymptomatic at birth or may cause a spectrum of disease ranging from relatively mild symptoms to multisystem involvement with severe and life-threatening complications. For some agents, disease is characterized by chronicity, recurrence, or both (in the mother and infant), and the agent may cause ongoing injury. Clinical signs and symptoms do not help make a specific etiologic diagnosis, but rather raise suspicion of an intrauterine infection and help distinguish these infections from acute bacterial infections that occur during labor and delivery. The following signs and symptoms are common to many of these agents (Table 98–5): intrauterine growth restriction, microcephaly or hydrocephalus, intracranial calcifications, chorioretinitis, cataracts, myocarditis, pneumonia, hepatosplenomegaly, direct hyperbilirubinemia, anemia, thrombocytopenia, hydrops fetalis, and skin manifestations, including petechiae, purpura, and vesicles. Many of these agents cause late sequelae, even if the infant is asymptomatic at birth. These adverse outcomes include sensorineural hearing loss, visual disturbances (including blindness), seizures, and neurodevelopmental abnormalities.

BACTERIAL SEPSIS

Neonates with bacterial sepsis may have either nonspecific signs and symptoms or focal signs of infection (Box 98–2 , Table 98–6), including temperature instability, hypotension, poor perfusion with pallor and mottled skin, metabolic acidosis, tachycardia or bradycardia, apnea, respiratory distress, grunting, cyanosis, irritability, lethargy, seizures, feeding intolerance, abdominal distention, jaundice, petechiae, purpura, and bleeding. The initial manifestation may involve only limited symptomatology and only one system, such as apnea alone or tachypnea with retractions or tachycardia, or it may be an acute catastrophic manifestation with multiorgan dysfunction. Infants should be re-evaluated over time to determine whether the symptoms have progressed from mild to severe. Later complications of sepsis include respiratory failure, pulmonary hypertension, cardiac failure, shock, renal failure, liver dysfunction, cerebral edema or thrombosis, adrenal hemorrhage and/or insufficiency, bone marrow dysfunction (neutropenia, thrombocytopenia, anemia), and disseminated intravascular coagulopathy (DIC).

A variety of noninfectious conditions can occur together with neonatal infection or can make the diagnosis of infection more difficult. For example, RDS secondary to surfactant deficiency can coexist with bacterial pneumonia. Because bacterial sepsis can be rapidly progressive, the physician must be alert to the signs and symptoms of possible infection and initiate diagnostic evaluation and empirical therapy in a timely manner. The differential diagnosis of many of the signs and symptoms that suggest infection is extensive; these noninfectious disorders must also be considered as the diagnostic evaluation proceeds (Table 98–7).

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

The clinical manifestations of infection depend on the virulence of the infecting organism and the body's inflammatory

TABLE 98.5-5 -- Clinical Manifestations of Transplacental Infections

Manifestation	Pathogen

CMV = cytomegalovirus; VZV = varicella-zoster virus; HSV = herpes simplex virus.

response to that agent. The term *systemic inflammatory response syndrome* (SIRS) is most frequently used to describe this unique process of infection and the subsequent systemic response (Chapters 57.2 and 163). In addition to infection, SIRS may result from trauma, hemorrhagic shock, other causes of ischemia, and pancreatitis.

- Pallor
- Petechiae, purpura
- Bleeding

Patients with SIRS have a spectrum of clinical symptoms that represent progressive stages of the pathologic process. In adults, SIRS is defined by the presence of two or more of the following: (1) fever or hypothermia, (2) tachycardia, (3) tachypnea, and (4) abnormal WBC count or an increase in immature forms. In neonates and pediatric patients, SIRS is manifested as temperature instability, respiratory dysfunction (altered gas exchange, hypoxemia, acute respiratory distress syndrome [ARDS]), cardiac dysfunction (tachycardia, delayed capillary refill, hypotension), and perfusion abnormalities (oliguria, metabolic acidosis, Box 98–3). Increased vascular permeability results in capillary leak into peripheral tissues and the lungs, with resultant pulmonary and peripheral edema. DIC results in the more severely affected cases. The cascade of escalating tissue injury may lead to multisystem organ failure and death.

Fever.

Only about 50% of infected newborn infants have a temperature higher than 37.8°C (axillary). Fever in newborn infants does not always signify infection; it may be caused by increased ambient temperature, isolette or radiant warmer malfunction, dehydration, central nervous system (CNS) disorders, hyperthyroidism, familial dysautonomia, or ectodermal dysplasia. A single temperature elevation is infrequently associated with infection; fever sustained over 1?hr is more likely to be due to infection. Most febrile infected infants have additional signs compatible with infection, although a focus of infection may not be apparent. Acute febrile illnesses occurring later in the neonatal period may be caused by urinary tract infection, meningitis, pneumonia, osteomyelitis, or gastroenteritis, in addition to bloodstream infection, thus underscoring the importance of a diagnostic evaluation that includes

blood culture, urine culture, lumbar puncture, and other studies as indicated (see later). Many agents may cause these late infections, including HSV, enteroviruses, respiratory syncytial virus, and bacterial pathogens. In premature infants, hypothermia or temperature instability is more likely to accompany infection.

Rash.

Cutaneous manifestations of infection include impetigo, cellulitis, mastitis, omphalitis, and subcutaneous abscesses. Ecthyma gangrenosum is indicative of infection with *Pseudomonas* species. The presence of small salmon-pink papules suggests *L. monocytogenes* infection. A vesicular rash is consistent with herpesvirus infection. The mucocutaneous lesions of *Candida albicans* are discussed elsewhere (Chapter 215.1). Petechiae and purpura may have an infectious cause. Purple papulonodular lesions are referred to as “blueberry-muffin” rash and represent dermal erythropoiesis. Causes include congenital viral infections (CMV,

rubella, and parvovirus), congenital neoplastic disease, and Rh hemolytic disease.

Omphalitis.

Omphalitis is a unique neonatal infection resulting from inadequate care of the umbilical cord. The umbilical stump is colonized by bacteria from the maternal genital tract and the environment. The necrotic tissue of the umbilical cord is an excellent medium for bacterial growth. Omphalitis may remain a localized infection or may spread to the abdominal wall, the peritoneum, the umbilical or portal vessels, or the liver. Abdominal wall cellulitis or necrotizing fasciitis with associated sepsis and a high mortality rate may develop in infants with omphalitis.

Box 98.5-3. Definitions of SIRS and Sepsis: Pediatric Patients

SIRS: The systemic inflammatory response to a variety of clinical insults, manifested by 2 or more of the following conditions:

- Temperature instability <35℃ or >38.5℃
- Respiratory dysfunction
  - Tachypnea >2 SD above the mean for age
  - Hypoxemia (PaO_2 <70?mm?Hg on room air)
- Cardiac dysfunction
  - Tachycardia >2 SD above the mean for age
  - Delayed capillary refill >3 sec
  - Hypotension >2 SD below the mean for age
- Perfusion abnormalities
  - Oliguria (urine output <0.5 mL/kg/hr)
  - Lactic acidosis (elevated plasma lactate and/or arterial pH <7.25)
  - Altered mental status

Sepsis: The systemic inflammatory response to an infectious process

From Adams-Chapman I, Stoll BJ: Systemic inflammatory response syndrome. Semin Pediatr Infect Dis 2001; 12:5–16.

Tetanus (see Chapter 194).

Neonatal tetanus is an important neonatal infection in several developing countries. It results from unclean delivery and unhygienic management of the umbilical cord in an infant born to a mother who has not been immunized against tetanus. The surveillance case definition of neonatal tetanus requires the ability of a newborn to suck at birth and for the first few days of life, followed by an inability to suck starting between 3 and 10 days of age, difficulty swallowing, spasms, stiffness, seizures, and death. Bronchopneumonia, presumably resulting from aspiration, is a common complication and cause of death. Neonatal tetanus is a preventable disease. It can be prevented by immunizing mothers before or during pregnancy and by ensuring a clean delivery, sterile cutting of the umbilical cord, and proper cord care after birth.

Pneumonia.

Early signs and symptoms of pneumonia may be nonspecific, including poor feeding, lethargy, irritability, cyanosis, temperature instability, and the overall impression that the infant is not well. Respiratory symptoms include grunting, tachypnea, retractions, flaring of the alae nasi, cyanosis, apnea, and progressive respiratory failure. If the infant is premature, these signs of progressive respiratory distress may be superimposed on surfactant deficiency (RDS) or BPD. If an infant is being ventilated at the time of infection, the most prominent change may be the need for an increase in ventilatory support.

Signs of pneumonia on physical examination, such as dullness to percussion, change in breath sounds, and the presence of rales or rhonchi, are very difficult to appreciate in a neonate. Roentgenograms of the chest may reveal new infiltrates or an effusion, but if the neonate has underlying RDS or BPD, it is very difficult to determine whether the radiographic changes represent a new process or worsening of the underlying disease.

The progression of neonatal pneumonia can be variable. Fulminant infection is most commonly associated with pyogenic organisms such as GBS (see Chapter 169). Onset may be during the first hours or days of life, with the infant often manifesting rapidly progressive circulatory collapse and respiratory failure. With early-onset pneumonia, the clinical course and radiographs of the chest may be indistinguishable from severe RDS.

In contrast to the rapid progression of pneumonia when caused by pyogenic organisms, older infants with community-acquired infection often have an indolent course. The onset is usually preceded by upper respiratory tract symptoms or conjunctivitis. A nonproductive cough ensues, and the degree of respiratory compromise is variable. Fever is usually absent, and radiographic examination of the chest shows focal or diffuse interstitial pneumonitis. This infection has been called the “afebrile pneumonia syndrome” and is generally caused by *C. trachomatis*, CMV, *Ureaplasma urealyticum*, or one of the respiratory viruses. Although *Pneumocystis carinii* was implicated in the original description of this syndrome, its etiologic role is now in doubt, except in newborns infected with HIV.

98.6 Diagnosis

The maternal history may provide important information about maternal exposure to infection, maternal immunity (natural or acquired), maternal colonization, and obstetric risk factors (prematurity, prolonged ruptured membranes, maternal chorioamnionitis) (Box 98–4).

Sexually transmitted diseases (STDs) that infect a pregnant woman are of particular concern to the fetus and newborn because of the possibility for intrauterine or perinatal transmission. All pregnant women and their partners should be queried about a history of STDs and counseled about the potential adverse effects on the mother and child and the importance of

Box 98.6-4. Evaluation of a Newborn for Infection or Sepsis

HISTORY (SPECIFIC RISK FACTORS)

- Maternal infection during gestation or at parturition (type and duration of antimicrobial therapy)
    - Urinary tract infection
    - Chorioamnionitis
- Maternal colonization with GBS, *Neisseria gonorrhoeae*, herpes simplex
- Gestational age/birthweight
- Multiple birth
- Duration of membrane rupture
- Complicated delivery
- Fetal tachycardia (distress)
- Age at onset (in utero, birth, early postnatal, late)
- Location at onset (hospital, community)
- Medical intervention

Location at onset (hospital, community)

Medical intervention

- Vascular access
- Endotracheal intubation
- Parenteral nutrition
- Surgery

EVIDENCE OF OTHER DISEASES

Congenital malformations (heart disease, neural tube defect)

Respiratory tract disease (RDS, aspiration)

Necrotizing enterocolitis

Metabolic disease, e.g., galactosemia

EVIDENCE OF FOCAL OR SYSTEMIC DISEASE

General appearance, neurologic status

Abnormal vital signs

Organ system disease

Feeding, stools, urine output, extremity movement

LABORATORY STUDIES

Evidence of Infection

Culture from a normally sterile site (blood, CSF, other)

Demonstration of a microorganism in tissue or fluid

Antigen detection (urine, CSF)

Demonstration of a microorganism in tissue or fluid

Antigen detection (urine, CSF)

Maternal or neonatal serology (syphilis, toxoplasmosis)

Autopsy

Evidence of Inflammation

Leukocytosis, increased immature/total neutrophil count ratio

Acute-phase reactants: CRP, ESR

Cytokines: interleukin 6

Pleocytosis in CSF or synovial or pleural fluid

Disseminated intravascular coagulation: fibrin split proucts

Evidence of Multiorgan System Disease

Metabolic acidosis: pH, P_{CO_2}

Pulmonary function: P_{O_2} , P_{CO_2}

Renal function: BUN, creatinine

Hepatic injury/function: bilirubin, ALT, AST ammonia, PT, PTT

Bone marrow function: neutropenia, anemia, thrombocytopenia

GBS = group B streptococci; RDS = respiratory distress syndrome; CSF = cerebrospinal fluid; CRP = C-reactive protein; ESR = erythrocyte sedimentation rate; P_{CO_2} = partial pressure of carbon dioxide; P_{O_2} = partial pressure of oxygen; BUN = blood urea nitrogen; ALT = alanine aminotransferase; AST = aspartate aminotransferase; PT = prothrombin time; PTT = partial thromboplastin time.

pressure of carbon dioxide; P_{O_2} = partial pressure of oxygen; BUN = blood urea nitrogen; ALT = alanine aminotransferase; AST = aspartate aminotransferase; PT = prothrombin time; PTT = partial thromboplastin time.

*Diseases that increase the risk of infection or may overlap with signs of sepsis.

avoiding infection during pregnancy. Women should also be counseled about the need for timely diagnosis and therapy for infections during pregnancy. The CDC recommends the following screening tests and appropriate treatment of infected mothers: (1) All pregnant women should be offered voluntary and confidential HIV testing at the 1st prenatal visit. For women at high risk of infection during pregnancy (multiple sexual partners or STDs during pregnancy, intravenous drug use), repeat testing in the 3rd trimester is recommended. (2) A serologic test for syphilis should be performed on all pregnant women at the 1st prenatal visit. Repeat screening early in the 3rd trimester and again at delivery is recommended for women who had positive serology in the 1st trimester and for those at high risk for

infection during pregnancy. (3) A serologic test for hepatitis B surface antigen (HBsAg) should be performed at the 1st prenatal visit and repeated late in pregnancy in those who are initially negative but at high risk for infection. (4) A maternal genital culture for *C. trachomatis* should be performed at the 1st prenatal visit. Young women (under 25 yr) and those at increased risk for infection (new or multiple partners during pregnancy) should be retested during the 3rd trimester. (5) A maternal genital culture for *Neisseria gonorrhoeae* should be performed at the 1st prenatal visit for women at risk and for those who live in areas with a high prevalence of gonorrhea. Repeat testing in the 3rd trimester is recommended for those at continued risk. (6) Evaluation for bacterial vaginosis should be considered at the 1st prenatal visit for asymptomatic women at high risk for preterm labor. (7) The CDC has recommended universal screening for rectovaginal GBS colonization of all pregnant women at 35–37 wk gestation and a screening-based approach to selective intrapartum antibiotic prophylaxis against GBS (Fig. 98–6 ; also see Chapter 169).

SUSPECTED INTRAUTERINE INFECTION

The acronym *TORCH* refers to *t*oxoplasmosis, *o*ther agents, (syphilis, etc.), *r*ubella, *C*MV, and *H*SV. Although the term may be helpful in remembering some of the etiologic agents of intrauterine infection, the TORCH battery of serologic tests has a poor diagnostic yield, and appropriate diagnostic studies should be selected for each etiologic agent under consideration. CMV and HSV require culture or polymerase chain reaction (PCR) methods, whereas syphilis, toxoplasmosis, and rubella are diagnosed by specific serologic methods (see Box 98–4).

Figure 98.6-6 Revised perinatal group B streptococcus (GBS) prevention guidelines. IAP = intrapartum antibiotic prophylaxis. (From Schrag S, Gorwitz R, Fultz-Butts K, Schuchat A: Prevention of perinatal group B streptococcal disease: Revised guidelines from CDC MMWR MorbMortalwkly Rep2002;51 [RR-11]:1.)

In most cases of suspected fetal infection, concern is not raised until the pregnant woman has been ill for several weeks or, in retrospect, after delivery. At this time, the maternal immune response to the suspected pathogen may no longer reflect an acute infection—that is, the specific IgM response is no longer detectable and the IgG response has already reached a plateau. Many of the pathogen-specific IgM serologic assays require considerable skill to perform and tend to be less reliable than the more common IgG assays. As a result, IgM assays can be either falsely negative or falsely positive.

Neonatal antibody titers are often difficult to interpret because IgG is acquired from the mother by transplacental passage and determination of neonatal IgM titers to specific pathogens is technically difficult to perform and not universally available. IgM titers to specific pathogens have high specificity but only moderate sensitivity; they should not be used to preclude infection. Paired maternal and fetal-neonatal IgG titers with higher newborn IgG levels or rising IgG titers during infancy may be used to diagnose some congenital infections (e.g., congenital syphilis). Total cord blood IgM or IgA (neither are actively transported across the placenta to the fetus) and the presence of IgM–rheumatoid factor in neonatal serum are nonspecific tests for intrauterine infection.

If the likelihood of maternal infection with a known teratogenic agent is high, fetal ultrasound examination is strongly recommended. If the examination demonstrates either a physical abnormality or delayed growth for gestational age, examination of a fetal blood sample may be warranted. Cordocentesis can provide a sufficient sample for both total and pathogen-specific IgM assays or for PCR or culture. The total IgM value is important because the normal fetal IgM level is less than 5?mg/dL. Any elevation in total IgM may indicate an underlying fetal infection that has stimulated the fetal immune system. Specific IgM antibody tests are available for CMV, *T. pallidum*, parvovirus B19, and toxoplasmosis. However, IgM tests are useful only when the results are strongly positive. A negative pathogen-specific IgM finding does not rule that pathogen out as a cause of fetopathy.

If maternal serologic studies point to a specific pathogen, it is sometimes possible to detect the organism in amniotic fluid (culture, PCR). Amniocentesis can be performed and the fluid sent for analysis. The presence of CMV, *Toxoplasma,* or parvovirus in amniotic fluid indicates that the fetus is infected and at high risk, but it does not always mean that the fetus will have severe sequelae. In contrast, HSV and varicella-zoster virus (VZV) are rarely isolated from amniotic fluid samples. CMV, *Toxoplasma*, and parvovirus can also be identified from cordocentesis sampling.

Parvovirus does not grow in the cell cultures commonly available in the virology laboratory. Furthermore, an IgM response is not always detectable in women with primary infection. When fetal parvovirus infection is suspected, testing of fetal blood or amniotic fluid by PCR is recommended in addition to testing for a specific IgM response in the fetus. PCR may also be used for the diagnosis of toxoplasmosis, CMV, HSV, rubella, and syphilis.

Neonatal infections with CMV, *Toxoplasma,* rubella, HSV, and syphilis present a

diagnostic dilemma because (1) their clinical features overlap and may initially be indistinguishable, (2) disease may be inapparent, (3) maternal infection is often asymptomatic, (4) special laboratory studies may be needed, and (5) appropriate treatment of toxoplasmosis, syphilis, and HSV, which may reduce significant long-term morbidity, is predicated on an accurate diagnosis. Common shared features that should suggest the diagnosis of an intrauterine infection include intrauterine growth restriction, hematologic involvement (anemia, neutropenia, thrombocytopenia, petechiae, purpura), ocular signs (chorioretinitis, cataracts, keratoconjunctivitis, glaucoma, microphthalmos), CNS signs (microcephaly, hydrocephaly, intracranial calcifications), other organ system involvement (pneumonia, myocarditis, nephritis, hepatitis with hepatosplenomegaly, jaundice), and nonimmune hydrops. Diagnostic studies in newborns with suspected chronic intrauterine infection should specifically test for each diagnostic consideration. Systemic infections with CMV, HSV, and enteroviruses frequently involve the liver; if these infections are suspected, liver function tests should be performed. Neonatal HSV meningitis may be confirmed by isolation of the virus (or by PCR) from cerebrospinal fluid (CSF) or another site (skin, eye, mouth).

SUSPECTED BACTERIAL OR FUNGAL INFECTIONS

Bacterial or fungal infection is diagnosed by isolating the etiologic agent from a normally sterile body site (blood, CSF, urine, joint fluid). Obtaining two blood culture specimens by venipuncture from different sites avoids confusion caused by skin contamination and increases the likelihood of bacterial detection. Samples should be obtained from an umbilical catheter only at the time of initial insertion. A peripheral venous sample should also be obtained when blood is drawn for culture from central venous catheters. Although blood cultures are usually the basis for a diagnosis of bacterial infection, the bacteremic phase of the illness may be missed by poor timing or inadequate blood sample size. Low-level bacteremia (<10 colony-forming units/mL) has been observed in some infants from birth to 2 mo of age with positive cultures. Current automated blood culture systems (BACTEC, Becton Dickinson; BacT/Alert, Organon Teknika), which continuously monitor blood cultures by checking each bottle every few minutes, have led to earlier detection of bacterial growth.

Bacterial antigen detection kits are available for a variety of organisms (GBS, *S. pneumoniae*) but are infrequently used because they are not as sensitive as blood cultures and false-positive results can occur. They may be helpful in the diagnosis of meningitis in the presence of previous antibiotic therapy. DNA probes and PCR technology are available for a number of viral and bacterial agents, but they are more often used in reference or research laboratories than in standard hospital microbiology laboratories. In the future, DNA array technology may permit the near instantaneous detection of pathogens from clinical samples.

Documentation of a positive blood culture is the first diagnostic criterion that must be met for sepsis (see Box 98–4). However, it is important to note that some patients with bacterial infection may have negative blood cultures (“clinical infection”), and other approaches to identification of infection are needed. Although the total WBC count and differential and the ratio of immature to total neutrophils have limitations in sensitivity and specificity, an immature-to-total neutrophil ratio of 0.2 or greater suggests bacterial infection. Neutropenia is more common than neutrophilia in severe neonatal sepsis, but neutropenia also occurs in association with maternal hypertension, preeclampsia, and intrauterine growth restriction. Thrombocytopenia is a nonspecific indicator of infection. Tests to demonstrate an inflammatory response include C-reactive protein, haptoglobin, fibrinogen, and various inflammatory cytokines, including IL-6 and IL-8. It is unclear which surrogate markers for infection are most helpful in determining when infants require a complete course of therapy in the absence of positive culture results.

When the clinical findings suggest an acute infection and the focus is unclear, additional studies should be performed, including, in addition to blood cultures, lumbar puncture, urine examination, and a chest roentgenogram. Urine should be collected by catheterization or suprapubic aspiration; urine culture for bacteria can be omitted in suspected early-onset infections because hematogenous spread to the urinary tract is rare at this point. Examination of the buffy coat with Gram or methylene blue stain may demonstrate intracellular pathogens. Demonstration of

bacteria and inflammatory cells in Gram-stained gastric aspirates on the 1st day of life may reflect maternal amnionitis, which is a risk factor for early-onset infection. Stains of endotracheal secretions in infants with early-onset pneumonia may demonstrate intracellular bacteria, and cultures may reveal either pathogens or upper respiratory tract flora. Careful examination of the placenta can be helpful in the diagnosis of both chronic and acute intrauterine infections.

Diagnostic evaluation is indicated for asymptomatic infants born to mothers with chorioamnionitis. The probability of neonatal infection correlates with the degree of prematurity and bacterial contamination of the amniotic fluid. In an asymptomatic term infant whose mother has chorioamnionitis, two blood cultures should be performed and presumptive treatment initiated. Lumbar puncture is not necessary because term infants with bacterial meningitis are almost always symptomatic. If the blood culture result is positive or if the infant becomes symptomatic, lumbar puncture should then be performed. If the mother has been treated with antibiotics for chorioamnionitis, the newborn's blood culture result is usually negative, and the clinician must rely on clinical observation and other laboratory tests.

The diagnosis of pneumonia in a neonate is usually presumptive; microbiologic proof of infection is generally lacking because lung tissue is not easily cultured. Although some rely on the results of bacteriologic culture of material obtained from the trachea as “proof” of cause, interpretation of such cultures has many pitfalls. These cultures often reflect upper respiratory tract commensal organisms and may have no etiologic significance. Even cultures performed on material obtained by bronchoalveolar lavage in a neonate are unreliable because the tiny bronchoscopes used in neonates cannot be protected from contamination as they are introduced into the distal airways. Short of tissue obtained by lung biopsy, the only reliable bacteriologic cultures are those obtained from blood or pleural fluid. Unfortunately, blood culture results are usually negative, and sufficient pleural fluid for culture is rarely present. Interpretation of fungal cultures is associated with the same problems as for bacterial cultures. Cultures of respiratory secretions for *U. urealyticum* and other genital *Mycoplasma* species are of little value because normal neonates are often colonized with these agents as a result of contamination with secretions from the maternal

genital tract. Cultures for respiratory viruses and *C. trachomatis* may be valuable; they are never indigenous flora, and isolation of them therefore suggests an etiologic role.

Serologic tests may be helpful in evaluating neonates with suspected pneumonia. Although no serologic tests are useful for bacteria or fungi, reliable tests for respiratory viruses and *C. trachomatis* are available. Serologic tests for *U. urealyticum* are complicated and technically demanding and are therefore not clinically useful at this time. Other tests of potential value in evaluating neonates with possible infectious pneumonitis are discussed under diagnosis of infections (see Chapter 160). The differential diagnosis of pneumonitis in neonates is broad and includes RDS, meconium aspiration syndrome, persistent pulmonary hypertension, diaphragmatic hernia, transient tachypnea of the newborn, congenital heart disease, and BPD.

The diagnosis of meningitis is confirmed by examination of CSF and identification of a bacterium, virus, or fungus by culture, antigen, or the use of PCR. Blood culture and a complete blood count are part of the initial evaluation because 70–85% of neonates with bacterial meningitis have positive results on blood culture. Examination and culture of CSF should be undertaken in infants with bacteremia. Lumbar puncture may be deferred in a severely ill infant if it would further compromise respiratory status. In these situations, blood culture should be performed and treatment initiated for presumed meningitis until lumbar puncture can be safely performed.

Normal, uninfected infants from 0–4 wk of age may have elevated CSF protein levels of 84 ± 45?mg/dL, glucose of 46 ± 10?mg/dL, and elevated CSF leukocyte counts of 11 ± 10 with the 90th percentile being 22. The proportion of polymorphonuclear leukocytes is 2.2 ± 3.8%, with the 90th percentile being 6. Elevated CSF protein levels and leukocyte counts and hypoglycorrhachia may develop in preterm infants after intraventricular hemorrhage. Many nonpyogenic congenital infections can also produce alterations in CSF protein and leukocytes (toxoplasmosis, CMV, HSV, syphilis).

Gram stain of CSF yields a positive result in most patients with bacterial meningitis. The leukocyte count is usually elevated, with a predominance of neutrophils (>70–90%); the number is often greater than 1,000 but may be less than 100 in infants with neutropenia or early in the disease. Microorganisms are recovered from most patients who have not been pretreated with antibiotics. Bacteria have also been isolated from CSF that did not have an abnormal number of cells (<25) or an abnormal protein level (<200?mg/dL), thus underscoring the importance of performing a culture and Gram stain on all CSF specimens. Contamination of CSF by bacteremia after traumatic lumbar puncture may occur rarely. Culture-negative meningitis may be seen with antibiotic pretreatment, a brain abscess, or infection with *Mycobacterium hominis, U. urealyticum*, *Bacteroides fragilis*, enterovirus, or HSV. Head ultrasonography or CT with contrast enhancement may be helpful in diagnosing ventriculitis and brain abscess.

98.7 Treatment

Treatment of suspected bacterial infection is determined by the pattern of disease and the organisms that are common for the age of the infant and the flora of the nursery. Once appropriate cultures have been obtained, intravenous or intramuscular antibiotic therapy should be instituted immediately. Initial empirical treatment of early-onset bacterial infections should consist of ampicillin and an aminoglycoside (usually gentamicin). Nosocomial infections acquired in a NICU are more likely to be caused by staphylococci, various Enterobacteriaceae, *Pseudomonas* species, or *Candida* species. Thus, an antistaphylococcal drug, methicillin or nafcillin for *S. aureus* or vancomycin for coagulase-negative staphylococci or methicillin-resistant *S. aureus*, should be substituted for ampicillin. A history of recent antimicrobial therapy or the presence of antibiotic-resistant infections in the NICU suggests the need for a different aminoglycoside agent (amikacin). When the history or the presence of necrotic skin lesions suggests *Pseudomonas* infection, initial therapy should be piperacillin, ticarcillin, carbenicillin, or ceftazidime and an aminoglycoside. The use of antifungal therapy should be considered in VLBW infants who have had previous antibiotic therapy, may have mucosal colonization with *C. albicans*, and are at high risk for invasive disease (see Chapter 215.1). Doses of commonly used antibiotics are provided in Table 98–8 . Peak and trough levels of gentamicin (peak, 5–10?µg/mL; trough, <2?µg/mL) and vancomycin (peak, 25–40?µg/mL; trough, <10?µg/mL) are useful to ensure therapeutic levels and minimize toxicity if administered for more than 2–3 days.

Once the pathogen has been identified and antibiotic sensitivities determined, the most appropriate drug or drugs should be selected. For most gram-negative enteric bacteria, ampicillin and an aminoglycoside or a third-generation cephalosporin (cefotaxime or ceftazidime) should be used. Enterococci should be treated with both a penicillin (ampicillin or piperacillin) and an aminoglycoside because the synergy of both drugs is needed. Ampicillin alone is adequate for *L. monocytogenes*, and penicillin suffices for GBS. Clindamycin or metronidazole is appropriate for anaerobic infections.

TABLE 98.7-8 -- **Suggested Dosage Schedules for Antibiotics Used in Newborns**

Antibiotic	Route	Dosage (mg/kg) and Interval of Administration				
		Weight <1,200 g [*]	***Weight 1,200–2,000 g***		***Weight >2,000 g***

Adapted from Sáez-Llorens X, McCracken GH Jr: Clinical pharmacology of antibacterial agents. In Remington JS, Klein JO (editors): Infectious Diseases of the Fetus and Newborn Infant, 5th ed. Philadelphia, WB Saunders, 2001, pp 1419–1466.

* *Data from Prober CG.* The use of antibiotics in neonates weighing less than 1200 grams. Pediatr Infect Dis J *1990; 9:111.*

† *The appropriate dosage schedule should be based on serum concentration measurements; some experts recommend once-daily dosing.*

‡ *Suggested doses based on anecdotal clinical experience.*

§ *A loading intravenous dose of 15?mg/kg followed 24 hr later (term infants) and 48 hr later (preterm infants) by 7.5?mg/kg every 12 hr has been suggested by other investigators.*

Dosages of meropenem suggested are the same as those of imipenem.

Third-generation cephalosporins such as cefotaxime are valuable additions for treating documented neonatal sepsis and meningitis because (1) the minimal inhibitory concentrations needed for treatment of gram-negative enteric bacilli are much lower than those for the aminoglycosides, (2) excellent penetration into CSF occurs in the presence of inflamed meninges, and (3) much higher doses can be given. The end result is much higher bactericidal titers in serum and CSF than achievable with ampicillin-aminoglycoside combinations. However, the routine use of third-generation cephalosporins for suspected sepsis in NICU patients is inappropriate because of the potential for rapid emergence of resistant organisms.

The emergence of antibiotic resistance among pathogens that infect newborns is of great concern. Vancomycin-resistant enterococci and vancomycin-insensitive *S. aureus* are particularly worrisome. Guidelines to limit the use of vancomycin must be followed. Although vancomycin use cannot be avoided in neonatal units where methicillin-resistant *S. aureus* is endemic, use can be reduced by limiting empirical therapy to patients with a high suspicion of severe infection with coagulase-negative staphylococci (e.g., severely ill neonate with an indwelling intravascular catheter) and discontinuing therapy after 2–3 days when blood cultures are negative. The rational use of antibiotics in neonates involves using narrow-spectrum drugs when possible, treating infection and not colonization, and limiting the duration of therapy.

Therapy for most bloodstream infections should be continued for a total of 7–10 days or for at least 5–7 days after a clinical response has occurred. A blood culture taken 24–48?hr after initiation of therapy should yield negative results. If the culture results are positive, the possibility of an infected indwelling catheter, endocarditis, an infected thrombus, an occult abscess, subtherapeutic antibiotic levels, or resistant organisms should be considered. A change in antibiotics, longer duration of therapy, or removal of the catheter may be indicated.

Treatment of newborn infants whose mothers received antibiotics during labor should

be individualized. If in utero infection is likely, treatment of the infant should be continued until it is shown that no infection has occurred (the infant remains asymptomatic for 24–72?hr) or clinical and laboratory evidence of recovery is apparent.

For pneumonia developing in the 1st 7–10 days of life, a combination of ampicillin and an aminoglycoside or cefotaxime is appropriate. Nosocomial pneumonia, generally manifested after this time, can be treated empirically with methicillin or vancomycin and a third-generation cephalosporin. *Pseudomonas*

pneumonia should be treated with an aminoglycoside combined with ticarcillin or ceftazidime. Pneumonia caused by *C. trachomatis* is treated with either erythromycin or trimethoprim-sulfamethoxazole; *U. urealyticum* infection is treated with erythromycin.

Presumptive antimicrobial therapy for bacterial meningitis should include ampicillin in meningitic doses and cefotaxime or gentamicin unless staphylococci are likely, which is an indication for vancomycin. Susceptibility testing of gram-negative enteric organisms is important because resistance to cephalosporins and aminoglycosides has been noted. Most aminoglycosides administered by parenteral routes do not achieve sufficiently high antibiotic levels in the lumbar CSF or ventricles to inhibit the growth of gram-negative bacilli. Therefore, some experts recommend a combination of intravenous ampicillin and a third-generation cephalosporin for the treatment of neonatal gram-negative meningitis. Cephalosporins should not be used as empirical monotherapy because *L. monocytogenes* and enterococcus are resistant to all cephalosporins.

Meningitis caused by GBS usually responds within 24–48?hr and should be treated for 14–21 days. Gram-negative bacilli may continue to grow from repeated CSF samples for 72–96?hr after therapy despite the use of appropriate antibiotics. Treatment of gram-negative meningitis should be continued for 21 days or for at least 14 days after sterilization of the CSF, whichever is longer. *P. aeruginosa* meningitis should be treated with ceftazidime. Metronidazole is the treatment of choice for infection caused by *B. fragilis*. Prolonged antibiotic administration, with or without needle drainage for treatment and diagnosis, is indicated for neonatal cerebral abscesses. CT scans are recommended for patients with suspected ventriculitis, hydrocephalus, or cerebral abscess (initial and follow-up assessments) and for those with an unexpectedly complicated course (prolonged coma, focal neurologic deficits, persistent or recurrent fever). Neonatal herpes meningoencephalitis should be treated with acyclovir, and empirical therapy should be considered in symptomatic infants with a CSF mononuclear pleocytosis. Pleconaril is the treatment of choice for severe enteroviral infections such as meningoencephalitis, carditis, or hepatitis. Treatment of candidal meningitis is discussed in Chapter 215 .

Treatment of sepsis and meningitis may be divided into antimicrobial therapy for the suspected or known pathogen and supportive care. Careful attention to respiratory and cardiovascular status is mandatory. Adequate oxygenation of tissues should be maintained; ventilatory support is frequently necessary for respiratory failure caused by sepsis, pneumonia, pulmonary hypertension, or ARDS. Refractory hypoxia and shock may require extracorporeal membrane oxygenation, which has reduced mortality rates in full-term infants with respiratory failure. Shock and metabolic acidosis should be identified and managed with fluid resuscitation and inotropic agents as needed. Corticosteroids should be administered only for adrenal insufficiency. Fluids, electrolytes, and glucose levels should be monitored carefully with correction of hypovolemia, hyponatremia, hypocalcemia, and hypoglycemia and limitation of fluids in those with inappropriate secretion of antidiuretic hormone. Hyperbilirubinemia should be monitored and treated aggressively with phototherapy and/or exchange transfusion because the risk of kernicterus increases in the presence of sepsis and meningitis. Seizures should be treated with anticonvulsants. Parenteral nutrition is needed for any infant who cannot sustain enteral feeding.

DIC may complicate neonatal septicemia. Platelet counts, hemoglobin, and clotting studies should be monitored. DIC is treated by management of the underlying infection, but if bleeding occurs, DIC may require fresh frozen plasma, platelet transfusions, or whole blood.

Because neutrophil storage pool depletion has been associated with a poor prognosis, a number of clinical trials of granulocyte transfusion therapy have been conducted, with variable results. The use of G-CSF or GM-CSF abolishes sepsis-induced neutropenia, but the effect of these cytokines on sepsis-related mortality is unclear. Modern leukapheresis techniques and the use of G-CSF to mobilize polymorphonuclear cells in healthy donors for use in granulocyte transfusion is a promising approach that needs further study. The use of intravenous immunoglobulin (IVIG) has been shown to decrease mortality in patients with sepsis; a meta-analysis of several trials recommended administration of a single dose of 500–750?mg/kg as adjunctive therapy. Selected IVIG preparations containing specific monoclonal antibodies are being studied.

It is important to remember that nonbacterial infectious agents can produce the syndrome of neonatal sepsis. HSV infection requires immediate specific treatment, as does systemic *Candida* infection. Treatment and other aspects of various non-bacterial infections are discussed in detail in other sections: TB (Chapter 197), syphilis (Chapter 200), genital mycoplasmas (Chapter 206), *C. trachomatis* (Chapter 208), *Candida* (Chapter 215), rubella (Chapter 226), enteroviruses (Chapter 229); parvovirus B19 (Chapter 230); HSV (Chapter 231), VZV (Chapter 232), and CMV (Chapter 234).

98.8 Complications and Prognosis

The sequelae of intrauterine infections with specific pathogens are described in their respective chapters. In general, complications of bacterial or fungal infections may be divided into those related to the inflammatory process per se and those that complicate underlying neonatal problems such as respiratory distress and fluid and electrolyte abnormalities.

Complications of bacteremic infections include endocarditis, septic emboli, abscess formation, septic joints with residual disability, and osteomyelitis and bone destruction. Recurrent bacteremia is rare (less than 5% of patients). Candidemia may lead to vasculitis, endocarditis, and endophthalmitis, as well as abscesses in the

kidneys, liver, lungs, and brain. Sequelae of sepsis may result from septic shock, DIC, or organ failure.

Mortality rates from the sepsis syndrome depend on the definition of sepsis. In adults, the mortality rate approaches 50%, and the rate in newborn infants is probably at least that high. Reported mortality rates in neonatal sepsis are as low as 10% because all bacteremic infections are included in the definition. Several studies have documented that the sepsis case fatality rate is highest for gram-negative and fungal infections (Table 98–9).

The case fatality rate for neonatal bacterial meningitis is between 20 and 25%. Many of these cases have associated sepsis. Risk factors for death or for moderate or severe disability include a duration of seizures for more than 72?hr, coma, necessity for the use of inotropic agents, and leukopenia. Immediate complications of meningitis include ventriculitis, cerebritis, and brain abscess. Late complications of meningitis occur in 40–50% of survivors and include hearing loss, abnormal behavior, developmental delay, cerebral palsy, focal motor disability, seizure disorders, and hydrocephalus. CT has demonstrated cerebritis, brain abscess, infarct, subdural effusions, cortical atrophy, and diffuse encephalomalacia in newborns surviving meningitis. A number of these sequelae may be encountered in infants with sepsis but without meningitis as a result of cerebritis or septic shock.

98.9 Prevention

A number of intrauterine infections are preventable through maternal immunization, including hepatitis B, rubella, and VZV. CMV vaccines are under study. Toxoplasmosis is preventable with appropriate diet and avoidance of exposure to cat feces.

TABLE 98.9-9 -- Infecting Pathogen vs Death Rate, Late-Onset Sepsis Review in VLBW Infants: NICHD Neonatal Research Network, September 1, 1998 through August 31, 2000

Organism*	N	Death n†
All gram-positive organisms	**905**	**101 (11.2%)**
Staphylococcus—coagulase negative	606	55 (9.1%)
Staphylococcus aureus	99	17 (17.2%)
Group B streptococcus	32	7 (21.9%)
All other streptococci	65	7 (10.8%)

* *Organisms found on the last positive blood culture before death or discharge. Organism counts differ from those based on the 1st positive blood culture (Table 98–5) because of multiple sepsis episodes. Death rates are not shown for every organism found.*
† *The odds ratios for death, with control for gestational age, study center, race, and sex, were as follows: gram-positive vs other infections, 0.26 (0.19–0.35), p < .001; gram-negative vs other infections, 3.5 (2.5–4.9), p < .001; and fungi vs other infections, 2.0 (1.3–3.0), p < .01.*

Malaria during pregnancy can be minimized with chemoprophylaxis. Congenital syphilis is preventable by timely diagnosis and appropriate early treatment of infected pregnant women.

Neonatal tetanus can be prevented by maternal tetanus immunization and proper care of the umbilical cord. Aggressive management of suspected maternal chorioamnionitis with antibiotic therapy during labor, along with rapid delivery of the

infant, reduces the risk of early-onset neonatal sepsis. Vertical transmission of GBS (Chapter 169) is significantly reduced by selective intrapartum chemoprophylaxis. Neonatal infection with *Chlamydia* can be prevented by identification and treatment of infected pregnant women (Chapter 208). Mother-to-child transmission of HIV is significantly reduced by maternal antiretroviral therapy during pregnancy, labor, and delivery and treatment of the infant after birth (Chapter 254).

PREVENTION OF NOSOCOMIAL INFECTION

Successful strategies to reduce rates of nosocomial infection, especially among VLBW infants in NICUs, are urgently needed. Principles for the prevention of nosocomial infection include adherence to universal precautions with all patient contact, avoiding nursery crowding and limiting nurse-to-patient ratios, strict compliance with handwashing, meticulous neonatal skin care, minimizing the risk of catheter contamination, decreasing the number of venipunctures and heelsticks, reducing the duration of catheter and mechanical ventilation days, providing education and feedback to nursery personnel, and ongoing monitoring and surveillance of nosocomial infection rates in the NICU (Box 98–5).

Most nosocomial infections in the NICU are bloodstream infections associated with an intravascular catheter. Catheters used in neonates include peripheral intravenous catheters, umbilical catheters, peripherally inserted central catheters, and surgically placed central venous catheters (CVCs). Efforts to reduce catheter-related infections include proper antisepsis of the skin before insertion of the catheter, sterile precautions during catheter insertion, aseptic technique when entering the line

Box 98.9-5. Principles for the Prevention of Nosocomial Infection in the Neonatal Intensive Care Unit

- Observe recommendations for universal precautions with all patient contact
    - Gloves
    - Gowns, mask, and isolation as indicated
- Nursery design engineering
    - Appropriate nursing:patient ratio
    - Avoid overcrowding and excessive workload
    - Readily accessible sinks, antiseptic solutions, soap, and paper towels
- Handwashing
    - Improve handwashing compliance
    - Wash hands before and after each patient encounter
    - Appropriate use of soap, alcohol-based preparations, or antiseptic solutions
    - Alcohol-based antiseptic solution at each patient bedside
    - Provide emollients for nursery staff
    - Education and feedback for nursery staff
- Minimizing risk of CVC contamination
    - Maximal sterile barrier precautions during CVC insertion
    - Local antisepsis with chlorhexidine gluconate
    - Minimize repeated entry into the

precautions during CVC insertion

Local antisepsis with chlorhexidine gluconate

Minimize repeated entry into the line for laboratory tests

Aseptic technique when entering the line

Minimize CVC days

Sterile preparation of all fluids to be administered via a CVC

Meticulous skin care

Encourage early and appropriate advancement of enteral feeding

Education and feedback for nursery personnel

Continuous monitoring and surveillance of nosocomial infection rates in the NICU

CVC = central venous catheter; NICU = neonatal intensive care unit.

From Adams-Chapman I, Stoll BJ: Prevention of nosocomial infections in the neonatal intensive care unit. Curr Opin Pediatr 2002; 14:157.

and minimizing repeated entry into the line for blood sampling, sterile preparation of fluids to be used with a CVC, and finally, minimizing the number of catheter days.

The skin is an important mechanical barrier to infection. VLBW infants are born with an ineffective epidermal barrier that results in increased transepidermal water loss and an increased risk for infection. Efforts to reduce traumatic injury to this immature skin are important, including a reduction in the number of heelsticks.

Handwashing remains the most important and effective means of reducing nosocomial infections. Several expert groups have established guidelines for effective handwashing. Antimicrobial soaps or alcohol-based preparations are recommended. Proper handwashing is essential before entering the NICU and before each patient contact. Barriers to compliance with handwashing include overcrowding, excessive patient-to-nurse ratios, poorly located sinks and inadequate supplies, lack of easy-to-use alcohol-based products at the bedside, concern about skin irritation, and inadequate knowledge, including the mistaken belief that the use of gloves obviates the need for handwashing.

Ongoing education of staff regarding practices that are likely to reduce nosocomial infections and active surveillance of infection rates are important components of nosocomial infection control.

Part 12 - Special Health Problems During Adolescence

Chapter 99 - The Epidemiology of Adolescent Health Problems

Renée R. Jenkins

Behavioral and psychosocial risks, including injuries, account for a substantial proportion of both the utilization of health care services by adolescents and the causes of morbidity and mortality. Adolescents make fewer visits to physicians for ambulatory care than does any other age group, yet school-aged children and adolescents are more likely than younger children to have unmet health needs and delayed medical care. Adolescents and young adults are less likely to be insured than all other age groups, and uninsured adolescents are 5 times as likely to lack a usual source of care, 4 times as likely to have unmet health needs, and twice as likely to go without a physician contact over the course of a year when compared with insured adolescents.

Most ambulatory visits for all age groups occur in physician offices, as compared with outpatient or emergency departments. However, in 1999, 15–24 yr olds received more of their ambulatory care in emergency rooms than did any other age group. In a survey of emergency room visits in the United States, 15–24 yr olds had the highest injury-related visit rate (18.3/100 persons). Although injuries predominated, females presented most often with complaints related to abdominal and chest pain. In the general ambulatory setting, health supervision (10%) and acne led the lists of diagnoses for 10–14 yr olds and 15–19 yr olds, respectively. Acute upper respiratory infections and normal pregnancy completed the list of the most common diagnoses.

Figure 99-1 Death rates among adolescents ages 15 to 19 by cause of death, 1980–98. (From Centers for Disease Control and Prevention, National Center for Health Statistics, National Vital Statistics System.)

Children with disabilities, as a group, access health care services more frequently than do nondisabled children, and adolescents represent the largest proportion of children who are disabled, 84.3 cases/1,000 (ages 12–17 yr) compared with 33.2 cases/1,000 for children younger than 6 yr of age. Overall, impairments of speech, special senses, and intelligence (primarily mental retardation) as well as respiratory disease (primarily asthma) make up the largest categories of disability diagnoses.

The leading causes of hospitalization in adolescents parallel the diagnoses of adolescents seen in the ambulatory setting, with the exception of mental disorders. Hospitalizations for mental disorders composed 17% of the top five discharge diagnoses in 1999 for 10–21 yr olds, with pregnancy and childbirth (55.5%), injuries (10%), diseases of the digestive system (10%), and respiratory tract diseases (7.5%) completing the list. The overall hospitalization rates have declined, with rates for 15–19 yr olds and 20–24 yr olds dropping 29% and 27%, respectively, for the years 1986 to 1996.

The health conditions having the greatest impact on the status of adolescent health are early unintended pregnancy, sexually transmitted diseases (STDs), mental disorders, injuries, and substance use and abuse. The trends in the frequency vary over time relative to prevention programs, legislative actions, and other societal factors. Teen births, at 49 births/1,000 in 2000, have declined steadily since 1991 (see Fig. 109–1) and surpassed the nadir of the early to mid-1980s of 50–53/1,000. Reportable sexually transmitted infections such as gonorrhea and syphilis have the highest prevalence in 15–24 yr olds. Rates for both diseases declined in 1999, compared with 1998 in 15–19 yr olds, but gonorrhea rates for young adults 20–24 yr increased. Chlamydia was the most common STD in adolescents and young adults in 1999, with 1,383/100,000 cases reported in 15–19 yr olds and 1,329/100,000 in 20–24 yr olds, both rates

reflecting an increase over the previous year. Less comprehensive survey data are available to identify trends for pelvic inflammatory disease, human papillomavirus, and human immunodeficiency virus infection.

Health destructive behavior, such as cigarette and marijuana smoking and the abuse of alcohol and recreational drugs (often in combination with driving), continues to present a serious problem for adolescents. Survey data demonstrate increases in marijuana and alcohol use until 1997, at which time the trend stabilized. See Chapter 105 .

Automobile and motorcycle accidents are the leading causes of adolescent morbidity and mortality. Sixteen to 19 yr olds compose 5% of licensed drivers and account for 15% of vehicular fatalities (see Chapter 50). Alcohol is a factor in approximately one

third of the fatal accidents involving adolescents. In addition, other factors such as less frequent use of seat belts and the presence of other teen passengers increases the severity of crashes involving teen drivers (Table 99–1). About 100 nonfatal injuries occur for every adolescent killed in a motor vehicle accident. These injuries are the leading cause of disability from head and spinal cord injuries for adolescents. Graduated licensing systems, more vigorously enforced drinking age laws, and nighttime driving restrictions are successful strategies to prevent mortality and morbidity.

Violent deaths and injuries have a significant impact on adolescents (Chapters 1 and 34). Homicides are the second leading cause of death for all adolescents and the most common cause of death for black males. Firearm deaths and injuries are a major contributor to these events. Although reliable national firearm injury data are not available, estimates range as high as 100 nonfatal violent assaults resulting in injury for each firearm death. The trend in the death rate has declined since 1980, reaching its nadir in 1985, then climbing to its height in 1993 (Fig. 99–1). From 1994 to 1998, the firearm homicide rates for black and Hispanic adolescent males declined substantially to 78 and 29 per 100,000, respectively.

International comparisons are becoming more readily available through the World Health Organization and the International Collaborative Effort (ICE) on Injury Statistics. These data are still limited and do not reflect information from Asian and African countries. Health behavior data on smoking

TABLE 99-1 -- **Percentage of Fatal Crashes by Characteristic, 1998**

	Driver Age		
	16	***17–19***	***20–49***
Driver error	80	75	62
Speeding	36	31	22
Single vehicle	41	37	30
3+ occupants	33	26	19

BAC = blood alcohol concentration.

From Insurance Institute for Highway Safety, Beginning Teenage Drivers, www.iihs.org/safety facts/teens/beginning drivers.htm, accessed 12/27/01.

and drinking in adolescents between ages 11 and 15 years show the United States ranking 24th out of 28 for daily smoking with 12% of 15 yr olds smoking daily. More than 25% of 15 yr olds in Austria, France, Germany, and Hungary smoke daily, leading the nations surveyed. Wales and Greece led the list for teenage drinking; reporting over 50% of 15 yr olds drinking weekly, whereas the United States reported about 23%. Mortality data reveal New Zealand with the highest injury death rate for 15–24 yr olds (Fig. 99–2). The United States leads all nations in the survey for firearm injury deaths.

Certain chronic diseases affecting adults have their origins during adolescence. Heart disease, diabetes, and respiratory conditions related to smoking are most common. Obesity is a major risk factor for cardiovascular diseases in adulthood but is also independently correlated with hypertension, hypercholesterolemia, diabetes mellitus, gallbladder disease, arthritis, and gout. As many as 22% of children aged 6–17 yr are considered overweight with a BMI (body mass index) more than the 85th percentile, whereas 10.9% are obese, with a BMI greater than the 95th percentile (see Chapter 43). Human immunodeficiency virus infection rises in its ranking as a cause of mortality from school-aged children through adulthood; by age 25–34 yr it represents the most common cause of death for black females and ranks among the top six causes of death for whites. According to the natural history of the disease, many of these infections were transmitted during adolescence or young adulthood.

Figure 99-2 Average annual injury death rates by mechanism among persons 15–24 years of age: Injury ICE countries, selected recent years. Chapter 100 - Delivery of Health Care to Adolescents

Renée R. Jenkins

The leading causes of death and disability among adolescents are preventable, suggesting that society has failed to address the health needs of this age group adequately. Further, teenagers who require medical treatment may not receive the care they need. Although the greatest proportion of health problems in adolescents are behaviorally related and less amenable to prevention and treatment by traditional medical services, there is still much that can be done to improve the effectiveness of adolescent health care. Access, confidentiality, and the delivery of age-appropriate care are the primary issues.

The Society for Adolescent Medicine identified seven criteria critical to adolescents' access to care. *Availability* addresses age-appropriate services at the community level and includes the creation and dissemination of provider education about adolescent preventive health guidelines. The ease of recognition or expectation that an adolescent's needs can be addressed in a setting relates to the *visibility* criterion. The *quality* of care should be kept at a guaranteed standard that is satisfactory to the patient as well. *Confidentiality* and access to care that requires consent by the adolescent should be available, while family involvement should be encouraged. Poor *affordability* is an obvious deterrent to access. Adolescents have the lowest annual rate of visits to office-based physicians compared with all other age groups (Fig. 100–1). For all age groups, including adolescents, individuals without insurance receive less health care, and insurance coverage is worse for adolescents and young adults. In 2000, adolescents (12–17 yr olds) were more likely to be uninsured than children under 12, 12.3% compared to 11.3%. Overall, the percentage of children and adolescents under 18 yr old without health insurance dropped from 12.5% in 1999 to 11.6% in 2000. Older adolescents and young adults (18–24 yr olds) were the least likely to have health insurance coverage, with 72.7% covered for some or all of 2000, more than double the rate of uninsured younger teenagers. Service providers who are *flexible* and adaptable recognize and respond to the cultural, ethnic, and social diversity issues of adolescents. Teens with multiple concerns and a broad range of health-related issues require *coordination* of medical, mental health, social, and other services.

The complexity and interaction of physical, cognitive, and psychosocial developmental processes during adolescence require sensitivity and skill on the part of the pediatrician and a greater number of contacts than is currently appreciated or financed. Health education and promotion as well as disease prevention should be

the focus of every visit with a teenager. To ensure that this is carried out comprehensively and systematically, guidelines have been promulgated from several organizations. However, the American Medical Association's Guidelines for Adolescent Preventive Services (GAPS) are the most evidence-based criteria (also see Chapter 5). A comparative analysis of the three sets of guidelines reveals more similarities than differences (Table 100–1). The GAPS guidelines, having been designed exclusively for adolescents, tend to be more specific in stating the criteria for intervention or referral. There is agreement across guidelines for the provision of a comprehensive physical examination (American Academy of Pediatrics [AAP] and Bright Futures [BF], annually; GAPS, three times during adolescence), screening for hypertension and obesity, and obtaining pertinent history for tobacco, alcohol, and drug use. If the teenager is sexually active, all guidelines recommend annual examination and

testing for sexually transmitted diseases. With varying specificity, recommendations direct physicians to obtain a history of depression; emotional, physical, or sexual abuse; and school performance. Those in high-risk groups should be screened for hypercholesterolemia and hyperlipidemia and for tuberculosis. Recommendations for immunizations include the following at the 11–12 yr old visit: diphtheria-tetanus if not immunized within the previous 5 yr; second trivalent measles-mumps-rubella vaccine

if there is no documentation of two vaccinations in early childhood, unless the adolescent is pregnant; and hepatitis B vaccination if not given by this age. Although meningococcal vaccine is not specifically discussed in the guidelines, the American Academy of Pediatrics recommends that freshman college students and their parents should be informed of the risk of meningococcal disease and the potential benefits of the immunization at the visit prior to matriculation. A companion document to the GAPS guidelines provides algorithms for each of the major preventive directives. Figure 100–2 (Figure Not Available) provides a sample using the algorithm for sexuality (also see Chapter 14). A consistent element to the approach of each of the guidelines is the role of parents in support of the adolescent's health and development. BF goes even further in recommending the support and interaction of the community in the adolescent's life.

The time spent on various elements of the screening will vary with the issues that surface during the assessment. For gay and lesbian youth, emotional and psychologic issues related to their experiences, from fear of disclosure to the trauma of homophobia, may direct the clinician to spend more time assessing emotional and psychologic supports in the young person's environment. For youth with chronic illnesses or special needs, the assessment of at-risk behaviors should not be omitted or de-emphasized by assuming they do not experience the “normal” adolescent vulnerabilities.

100.1 Legal Issues

In the United States, the right of a minor to *consent* to treatment without parental knowledge is governed by state laws. Some states have age limitations, generally around age 12–15 yr. Usually, the right to self-consent for treatment is granted through public health statutes when there is suspicion of a sexually transmitted disease. Because such diseases are often asymptomatic, this provision is generally interpreted as enabling the physician to perform an examination (including a pelvic examination for a young woman) in any sexually active adolescent solely on his or her own consent. In many states, adolescents may consent to receive care for drug abuse or mental health problems. The minor's right to *contraceptives* has not been

Figure 100.1-2 (Figure Not Available) Sexuality algorithm. (From Levenberg PB, Elster AB: *Guidelines for Adolescent Preventive Services. Clinical Evaluation and Management Handbook.* Chicago, American Medical Association, 1995. © 1995 American Medical Association.)

reviewed by the Supreme Court, although the right to privacy has been upheld (except in a decision allowing searches in schools without due process), and accordingly, most states permit the provision of contraceptives to teenagers on their own consent. Although attempts at restricting Title X–funded programs to provision of contraception only after parents have been informed has not been legislated, the publicity received by the proposal has left many teenagers with the mistaken notion that their parents will be informed if they seek birth control from any physician. The right of an adolescent to obtain an *abortion* without parental consent or over parental objection varies by state.

Minors are also exempt from the requirement of parental consent for medical treatment under the following circumstances:

1. *Emancipated minors*. These are children who live away from home, are no longer subject to parental control, are economically self-supporting, are married, or are members of the military.
2. *Emergencies*. In a medical emergency, a minor may be treated without consent of parents if, in the physician's judgment, the delay resulting from attempts to contact parents would jeopardize the life or health of the minor.
3. *Mature minor rule*. An emerging trend in the law is the recognition that many minors are sufficiently mature to understand the nature of their illness and the potential risks and benefits of proposed therapy and, therefore, should receive such treatment on their own consent. This is particularly the case when the care is low risk, will benefit the minor, and is within established medical practice standards. In these cases, the physician should document that the adolescent has acted in a responsible manner.

Legal policies regarding the confidentiality of information are less consistent than those governing consent. In general, the right to self-consent for health care carries with it the right to confidentiality about that information. Exceptions exist when there are mandatory reporting requirements, as in abuse cases, some legal provision requiring parental disclosure, or a self- imposed danger to the minor. When exceptions exist, this should be divulged to the adolescent and an opportunity for assent or agreement provided.

A chaperone should be present whenever an adolescent female patient is examined by a male physician. The necessity for chaperones in the situation of a female physician examining a male adolescent patient has not yet become an issue.

100.2 Screening Procedures

Interviewing the Adolescent (also see Chapters 5 and 17).

The preparation for a successful interview with an adolescent patient varies based on the prior history of the relationship with the patient. Patients, who are going from preadolescence to adolescence while seeing the same provider, and their parents should be guided through the transition. Although the rules for confidentiality are the same for new and continuing patients, the change in the physician-patient relationship, allowing more privacy during the visit and more autonomy in the health process, may be threatening for the parent as well as the adolescent. For new patients, the initial phases of the interview are more challenging given the need to establish rapport rapidly with the patient in order to meet the goals of the encounter. Issues of confidentiality and privacy should be explicitly stated along with the conditions under which that confidentiality may need to be altered, that is, in life- or safety-threatening situations. For new patients, the parents should be interviewed with the adolescent or before the adolescent to ensure that the adolescent does not perceive a breach of confidentiality. The physician who takes time to listen, avoids judgmental statements and the use of street jargon, and shows respect for the adolescent's emerging maturity will have an easier time communicating with him or her. The use of open-ended questions, rather than closed-ended questions, will further facilitate history-taking (e.g., the close-ended question, “Do you get along with your father?” leading to the answer, “Yes,” compared with the question, “What would you like to change in your relationship with your father?” which may lead to an answer such as “I would like to stop him from always putting me down, especially in front of my friends”).

The goals of the interview or clinical encounter are to establish an information base, identify problems and issues from the patient's perspective, and identify problems and issues from the perspective of the provider based on knowledge of the health and other issues relevant to the adolescent age group. The adolescent should be given an opportunity to express concerns and the reasons for seeking medical attention. The adolescent as well as the parent should also be given an opportunity to express the strengths and successes of the adolescent, in addition to communicating problems.

Barriers to an effective interview occur when the interviewer is distracted by other events or individuals in the office, when there are extreme time limitations obvious to either party, or when there is expressible discomfort with either the patient or the interviewer. The need for an interpreter when a patient is hearing impaired or if the patient and interviewer are not language-compatible provides a challenge but not necessarily a barrier under most circumstances. Observations during the interview can be useful to the overall assessment of the patient's maturity, presence or absence of depression, and the parent-adolescent relationship. Given the key role of a successful interview in the screening process, adequate training and experience should be sought by physicians wishing to give comprehensive care to adolescent patients.

Psychosocial Assessment.

A few questions should be asked to detect the adolescent who is having difficulty with peer relationships (e.g., “Do you have a best friend with whom you can share even the most personal secret?”); self-image (e.g., “Is there anything you would like to change about yourself?” or “What do you consider to be your best features?”); depression (e.g., “What do you see yourself doing 5 yr from now?” or “Are you ever so sad that you think of dying?”); school (e.g., “How are your grades this year compared with last year?” and “How many days have you been absent from school this year compared with last year?”); personal decisions (e.g., “Are you feeling pressured to engage in any behavior for which you do not feel you are ready?” or “Is there anything you would like to change in your relationship with your boyfriend, your father, and so on?”); and an eating disorder (e.g., “Do you ever feel that food controls you rather than vice versa?”). The GAPS material provides questions and algorithms to structure these assessments. Based on those algorithms, appropriate counseling or referrals are recommended for more thorough probing or for in-depth interviewing.

Physical Examination

AUDIOMETRY.

Highly amplified music of the kind enjoyed by many adolescents may result in hearing loss (see Chapter 627). Therefore, a hearing screening is recommended by the BF guidelines for adolescents who are exposed to loud noises regularly, have had recurring ear infections, or report problems.

VISION TESTING.

The pubertal growth spurt may involve the optic globe, resulting in its elongation and myopia in genetically predisposed individuals. Vision testing should, therefore, be performed in order to detect this problem before it affects school performance.

BLOOD PRESSURE DETERMINATION.

Criteria for a diagnosis of hypertension are based on age-specific norms that

increase with pubertal maturation (see Chapter 437). An individual whose blood pressure exceeds the 95th percentile for his or her age is suspect for having hypertension, regardless of the absolute reading. Those adolescents with blood pressure between the 90th and 95th percentiles should receive appropriate counseling relative to weight and have a follow-up examination in 6 mo. Those with

blood pressure below the 90th percentile should have their blood pressure measured on three separate occasions to determine the stability of the elevation before moving forward with an intervention strategy. The technique is important; false-positive results may be obtained if the cuff covers less than two thirds of the upper arm. The patient should be seated, and an average should be taken of the 2nd and 3rd consecutive readings, using the change rather than the disappearance as the diastolic pressure. Most adolescents with elevations of blood pressure have labile hypertension (see Chapter 437). If the blood pressure is below two standard deviations for age, anorexia nervosa and Addison disease should be considered.

SCOLIOSIS (also see Chapter 669.1).

Approximately 5% of male and 10–14% of female adolescents have a mild curvature of the spine. This is two to four times the rate in younger children. Scoliosis is typically manifested during the peak of the height velocity curve, at approximately 12 yr in females and 14 yr in males. Curves measuring greater than 10 degrees should be monitored by an orthopedist until growth is complete.

BREAST EXAMINATION.

Examination of the female adolescent's breasts is performed to detect masses (see Chapters 106 , 540 and 543), evaluate progression of sexual maturation, provide reassurance about development, and teach the technique of self-examination with the hope that this practice will continue into the higher risk later years. Although self-examination is promoted in two of the three guidelines, there is disagreement on the justification for promoting this routinely, given the rare instances of malignant breast masses in this age group.

SCROTUM EXAMINATION.

The peak incidence of germ cell tumors of the testes is in late adolescence and early adulthood. For that reason, palpation of the testes may have an immediate yield and should serve as a model for instruction of self-examination. Because varicoceles often appear during puberty, the examination also provides an opportunity to explain and reassure the patient about this entity (see Chapter 537).

PELVIC EXAMINATION. See Chapter 540 .

Laboratory Testing.

The increased incidence of iron-deficiency anemia after menarche mandates the performance of a *hematocrit* annually in young women with moderate to heavy menses. The reference standard for this test changes with progression of puberty, as estrogen suppresses erythropoietin (see Chapter 438). Populations with nutritional risk should also have the hematocrit monitored. Androgens have the opposite effect, causing the hematocrit to rise during male puberty; Sex Maturity Rating 1 males have an average hematocrit of 39%, whereas those who have completed puberty (Sexual Maturation Rating 5) have an average value of 43%. *Tuberculosis testing* on an annual basis is important in adolescents with risk factors, such as an adolescent with human immunodeficiency virus (HIV), living in the household with someone with HIV, the incarcerated adolescent, or those with other risk factors, because puberty has been shown to activate this disease in those not previously treated. Sexually active adolescents should undergo screening for *sexually transmitted diseases,* regardless of symptoms (see Chapter 110). During adolescence, a screening *urinalysis* is indicated for the sexually active male and female. Polymorphonuclear leukocytes in the urinary sediment suggest the possibility of either cervicitis, vaginitis, or an asymptomatic infection of the urinary tract in adolescent females and urethritis in adolescent males. *HIV testing* should be included for those at increased risk, e.g., a history of sexually transmitted diseases, more than one sex partner in the last 6 mo, bisexual and homosexual males, sexual partners of at-risk individuals, and intravenous drug users. *Papanicolaou smears* are also indicated in sexually active females, regardless of age, because 5–35/1,000 have early neoplastic changes. Technique is important; the practice of obtaining two successive cervical scrapes increases the yield by 26% over that obtained by a single cervical specimen. Augmentation or replacement of the traditional Pap smear is occurring with techniques (Thin-Prep, AutoPap, Papnet, cervicography, human papillomavirus [HPV] DNA testing) that increase the sensitivity of the screen and add the ability to identify HPV, a potential cervical cancer risk. Although not included in any of the guidelines, screening tests for *genetic defect carrier states,* such as sickle cell anemia, are commonly performed in affected populations. Age-appropriate counseling should be immediately available to ensure an opportunity to have questions answered and to have unspoken fears allayed. The use of *spirometry* screening for adolescents who smoke may, over time, serve as a deterrent if deterioration of respiratory status can be demonstrated.

100.3 Health Enhancement

The health status of adolescents may be enhanced by application of principles of prevention and anticipatory guidance. Prevention of infectious disease should include immunization and counseling. Prevention of sexually transmitted diseases and pregnancy is an important issue to be addressed in sexually active adolescents of both sexes. Prevention of the use of harmful illicit drugs and alcohol and the potential for related injuries should be reviewed. Prevention of automotive accidents and interpersonal conflicts ending violently, the leading killer of adolescents, and of smoking, the leading killer of adults, should also be discussed. Facilitating an optimal health outcome for the adolescent patient also includes supporting him or her in successfully negotiating adolescence through school, job, and personal and family relations.

Chapter 101 - Depression

Renée R. Jenkins

(See also Chapter 23 .)

Changes in mood are part of the normative developmental "adjustment" to changes in body, roles, and relationships in adolescence (also see Chapter 14). The challenge for a pediatrician is

to distinguish between these normative variations and disorders requiring mental health intervention. The widespread belief that major depression in children and adolescents is rare or self-limited has led to underdiagnosis and delayed treatment for approximately two thirds of adolescents with clinical depression.

Epidemiology.

The rate of depression in girls and boys changes significantly as a function of puberty. Gender variations are not characteristic of childhood depression, but depression is two to three times higher in postpubertal girls than in postpubertal boys. The lifetime prevalence of major depression is similar to adults and ranges between 15 and 20%. The co-occurrence of depression and another mental health disorder is reported from 40–70% of the time and is common in the adolescent age group. The most frequent co-morbid disorders are anxiety disorders, substance abuse, attention deficit disorder, and disruptive behavior disorders.

Etiology.

There appears to be an interactive effect of genetics and environment in major depressive disorders, with studies in adults suggesting individuals with a high genetic risk may be more vulnerable to adverse environmental stressors when compared with those with low genetic risk. A family history of depressed parents increases the adolescent's risk of lifetime major depression threefold. Other parenting factors such as marital conflict, inadequate parenting, or death of a parent are also associated with depression. Controversy exists about the temporal relationship of symptoms such as low self-esteem, high self-criticism, hopelessness, and social skill deficits to their role as risk factors or as a prodrome of depression.

Clinical Manifestations.

An adolescent who presents with school failure or another behavioral disorder may have an underlying depressive issue. The *Diagnostic and Statistical Manual for Primary Care, Child and Adolescent Version*, provides the clinical presentation of the range of "sadness" symptoms in young persons from the developmental variation, associated with bereavement or other stressors, through a sadness problem, and on to the full-blown disorder such as major depression. The characteristics of a sadness problem encompass (1) depressed or irritable mood, (2) diminished interest or pleasure, (3) weight loss or gain or failure to make expected weight gains, (4) insomnia or hypersomnia, (5) psychomotor agitation or retardation, (6) fatigue or energy loss, (7) feelings of worthlessness or excessive or inappropriate guilt, and (8) diminished ability to think or concentrate. The quality of these symptoms is less intense with a sadness problem as compared with major depression, and the impact on the adolescent's functioning is mild. When these symptoms occur daily for a period of 2 wk or longer, with or without recurrent thoughts of death and suicidal ideation, the diagnosis falls into the realm of a major depressive disorder. When these symptoms occur within 3 mo of an identifiable stressor, the presentation is considered an adjustment disorder with depressed mood. Persistent but less severe symptoms fall into the category of a dysthymic disorder. The depressed or irritable mood must persist for longer than a year accompanied by additional depressive clinical symptoms to meet the diagnostic criteria. Bipolar affective disorders are associated with child-onset and adolescent-onset depression in up to 30% of cases. The likelihood is increased with a positive family history of bipolar disorder and patients with a history of attention-deficit/hyperactivity disorder occurring with the presentation of depression. Bipolar disorders with depressive and manic features are of specific concern in the spectrum of depression diagnoses because of the potential for more exaggerated manic features being unmasked when these patients are treated with antidepressants.

DIFFERENTIAL DIAGNOSIS.

Physical and metabolic disturbances should be ruled out during the assessment of an adolescent with depressive symptoms. Hypothyroidism, nutritional deficiencies, a chronic infection such as mononucleosis, or a chronic systemic disease such as systemic lupus erythematosus should be considered. Substance abuse can mask the depression symptoms as well as imitate depression. A chronic learning disability leading to low self-esteem can also present with depressive-like symptoms.

OFFICE SCREENING FOR DEPRESSION.

Screening for depressive symptoms is recommended as a component of the routine health maintenance assessment for an adolescent. Although the diagnosis of a full depressive disorder is based on interviewing the adolescent and obtaining observational data from parents or primary caretakers, alertness during a medical evaluation can raise suspicion early in the course of the disorder. One strategy recommended in the American Medical Association's Guidelines for Adolescent Preventive Services is to pose a series of screening questions to determine whether

depressive symptoms at the level of mild, moderate to severe, or high risk exist. General questions such as, “Have you had fun during the past 2 weeks?” or “In general, are you happy with the way things are going for you these days?” alert the clinician to the need to ask more probing follow-up questions to elicit the presence or absence of diagnostic symptom criteria for depression. Another strategy is to use a depressive screening questionnaire such as the 21-question Beck Depression Inventory to confirm the clinical suspicion of depression. Screening for suicidal ideation must be included as a part of further evaluation in the presence of any depressive symptoms. Referral to a mental health professional for evaluation on an emergent basis is recommended under circumstances in which adolescents have current thoughts about killing themselves.

Treatment.

There are several therapeutic modalities for the treatment of depression, including individual and group therapy, family intervention, along with, or independent of, psychopharmacologic treatment (Chapters 28 and 28.2). Antidepressants are generally recommended for moderate to severe cases of major depression and in some cases of dysthymic disorders. The inability to demonstrate efficacy and potential toxicity have limited the use of tricyclic antidepressants in children and adolescents. Selective serotonin reuptake inhibitors are the primary medications used for major depression in children and adolescents. The role of the pediatrician in the timing of a referral to a mental health professional or in prescribing of antidepressants is determined by his or her training and experience in managing mental health problems. The education of parents and patients about depressive disorders is important in successful therapeutic interventions and in removal of the cultural stigma that may be associated with mental health therapy. The significance of timely intervention should be stressed, including the potential for a depressive disorder to disrupt the normal adolescent developmental process. An extended disruption can lead to impaired functioning even after recovery from the depressive episode. The importance of following early identification with prompt treatment cannot be overemphasized. See Chapter 28.2 for discussion of pharmacotherapy.

Prognosis.

In one survey of adolescents and young adults, more than one fifth of those with major depression reported ever attempting suicide, the most adverse outcome of a depressive disorder. An untreated major depressive episode can last up to 7–9 mo, with about 40% of cases recurring within 2 yr and 70% within 5 yr. The earlier the onset of depression, the more severe and recurrent the course. Appropriate use of antidepressants can improve depressive symptoms within 1 mo or less in some patients. Outcomes of untreated major depression persist into adulthood and are manifested as impaired psychologic, social, and academic functioning.

Chapter 102 - Suicide

Renée R. Jenkins

The recognition of risk factors for suicidal behavior is an important aspect in the prevention efforts directed toward adolescents, particularly those with mood disorders (see also Chapter 24).

Epidemiology.

Suicide is the third leading cause of death for all adolescents and young adults 15–24 yr old; it is the second leading cause of death for white males. Higher rates of suicide have also been reported in Alaskan, Asian-American, and Native American youth. From 1981 to 1998, the suicide rate for African-American males aged 10–19 yr doubled (2.9 to 6.1/100,000), further narrowing the gap between the rates for African-American and white males. The chronically ill adolescent is also at increased risk for suicide exacerbated by interpersonal difficulties and increased access to medications that can be used in a suicide attempt. Lithuania, the Russian Federation, and New Zealand lead the international community in reports of youth suicide with rates for males at or above 40/100,000. Although data on the rate of suicide attempts in the United States are not available, estimates range from 50 to 200 attempts per successful suicide. Males more frequently complete suicides, and females attempt suicide more often. Males use more violent methods, such as hanging, shooting, or wrist slashing, than females. Guns and firearms are the most prevalent method used to complete suicide among children and youth.

Etiology.

There are at least three proposed models to account for an increased risk of suicidal behavior in adolescents. The traditional psychiatric model of risk factors focuses on interpersonal

Figure 102-1 (Figure Not Available) This model suggests how suicide occurs and highlights types of targeted preventive interventions. (From American Academy of Child and Adolescent Psychiatry: Practice parameter for the assessment and treatment of children and adolescents with suicidal behavior. *J Am Acad Child Adolesc Psychiatry* 2001;40[7 Suppl]: 24S–51S.)

and family factors such as having a psychiatric disorder, family clustering of suicidal behavior, substance use and abuse, sexual and other abuse, and serotonin abnormalities. Low or below average levels of serotonin 5-HT (hydroxytryptamine) or the metabolite 5-HIAA (hydroxy-indoleacetic acid) may be associated with poor impulse control and linked to suicide and violent behavior. Parent-child conflict is more commonly identified as a risk factor in prepubertal adolescents. Gay and bisexual youth may be at greater risk by virtue of gender identity issues, increased use of substances, or the effects of victimization.

The “injury” model for increased suicide risk takes additional community risk factors into account such as local suicide and violence exposure rates, the availability of supportive social networks and suicide prevention programs in the community, and the availability of lethal means such as firearms.

A third approach that is more developmentally driven looks at suicidal risk in the context of other age-related problem behaviors, noting the high correlation between suicide attempts and lack of seatbelt use, carrying a gun in the 30 days prior to the suicide attempt, physical fights in the prior 12 mo, recent tobacco use, and intravenous drug use. Protective factors such as parent-family and school connectedness are emerging as factors modifying the risks for suicide and interpersonal violence. The complex set of factors represented in these approaches has a direct impact on the strategies taken in suicide prevention programs.

Clinical Manifestations.

Suicidal ideation alone is not necessarily a risk factor for suicidal behavior. As many as 12–25% of older children and adolescents express some form of suicidal ideation. The risk should be taken much more seriously when the ideation is accompanied by a specific plan. Self-administered suicide scales can be used for screening, but they tend to be oversensitive and underspecific and do not replace the clinical assessment. Psychologic autopsies following successful suicides have also uncovered the frequent occurrence of a stressful event, such as a disciplinary crisis, disappointment, or rejection, immediately preceding the suicide. When a suicide attempt is made, it is often difficult to assess the seriousness of the intent by the actual potency of the method. Beck and associates found medical lethality of methods to correlate poorly with seriousness of intent. There was, however, good correlation between the latter and the patient's expectation of lethality, which was often inaccurate. Although most adolescents who attempt suicide do not become successful, increased risk exists for later morbidity, mortality, depression, behavioral disturbances, and impaired social and academic skills.

Treatment.

Consultation with an experienced psychiatrist is essential in the assessment of every teenager who attempts suicide. The evaluation may result in an outpatient referral or hospitalization. When the three most serious risk factors—prior suicide attempt, mood disorder, and substance abuse—are present, there is no proof that hospitalization prevents repeated attempts and the ultimate completion of suicide.

However, a hospitalization may assist in resolution of an existing conflict and provide a secure setting in which the patient can have underlying problems addressed. Strategies to improve follow-up outpatient compliance include educating the family about adolescent suicidal behavior and its treatment and the use of a crisis therapist who also serves some case management functions between the family and the treatment provider.

Prevention.

The public health approaches to prevention can be targeted to the identification and risk level of the adolescent (Fig. 102–1 (Figure Not Available)) and include crisis hotlines, control of access to methods, indirect case finding through identifying "warning signs," direct case finding by primary care providers, providing guidelines to the media, and training professionals to improve skills in recognizing and treating mood disorders. Although considerable attention has been paid to the media impact of contagion and "copy-cat" suicides, clusters involving adolescents and young adults account for 1–5% of suicides in this age group in the United States.

Chapter 103 - Violent Behavior

Renée R. Jenkins

Interpersonal and community violence, physical abuse, and domestic violence lead to significant rates of injury and death for specific age, gender, and racial sectors of the population in the United States (also see Chapter 34). Youth and minority populations are disproportionately affected. Violent behavior permeates the youth culture, whether by media or personal experiences in the family, community, or school. For surveillance and research purposes, the Centers for Disease Control and Prevention has accepted a definition of a violent injury as "a threatened or actual use of physical force against a person or group that either results or is likely to result in injury or death." Youth are perpetrators of violence, victims of violence, or observers of violence with varying severity of impact on the individual. Violent acts may result in, or are contributed to by, mental health problems or disorders. Pediatricians are challenged to screen for these disorders and counsel or refer adolescents with serious disorders to mental health professionals. The public health and educational communities have launched a variety of violence prevention interventions to increase youth prosocial behavior and reduce violence as a societal problem.

Epidemiology.

In 1993–1994, the United States led the industrialized world in the number of youth deaths due to firearms, both homicide and unintentional firearm deaths (Fig. 103–1). From 1983–1993, the firearm homicide rate more than tripled from 5 to18/100,000. Since 1993 the rates of fatal and nonfatal firearm injuries have declined. Males are much more likely to be victims than females in fatal and nonfatal injuries; however, 15–24 yr old women have the highest proportion of injuries compared with women in other age groups.

The Youth Risk Behavior Surveillance System reported in 1999 that 17.3% of students (26.6% male and 6% female) carried a weapon such as a gun, knife, or club within the 30 days preceding the survey. However, compared with the baseline survey of 1991, weapon carrying had decreased. Nationally, 36.7% of students also reported being in a fight in the prior year, and this too has declined from 137/100 students/12 mo in 1993 to 106/100 students/12 mo in 1999. Forced sexual intercourse and dating violence were reported at similar rates, 8.8% of students. Females were more likely to report higher rates for both occurrences with the exception of similar rates of dating violence in white males and females (7.3% and

7.4% respectively).

Adolescents are more likely to be victims of violence than are any other age group (Fig. 103–2). In 2000, the victimization rate was 60.1/1,000 for 12–15 yr olds and 64.3/1,000 for 16–19 yr olds, a dramatic decline of almost 50% since 1994. Although adolescents are infrequently the age group that comes to mind when considering child abuse, adolescents make up almost one quarter of the child abuse and neglect cases in the United States

Figure 103-1 Firearm-related homicide rates by age; 36 high- and upper-middle-income countries by income group. (From Krug EG, Powell KE, Dahlberg LL: Firearm-related deaths in the United States and 35 other high- and upper-middle-income countries. *Int J Epidemiol* 1998;27:214.)

Figure 103-2 Violent crimes included are homicide, rape, robbery, and both simple and aggravated assault. The National Crime Victimization Survey redesign was implemented in 1993. The data before 1993 are adjusted to make them comparable with data collected since the redesign. The adjustment methods are described in *Criminal Victimization 1973–95*. Estimates for 1993 and beyond are based on collection year, whereas earlier estimates are based on data year. (From U.S. Department of Justice, Bureau of Justice Statistics, 2001.)

(see Chapter 35). Adolescents and children younger than 5 yr of age are the most likely victims of physical abuse that causes injury.

Etiology.

The theories to explain violence come from the perspective of varying disciplines. The development psychopathology model of Mofitt identifies two types of antisocial youth: one that is life course–persistent and one that is life course–limited. Adolescent-limited offenders have no childhood aberrant behaviors and are more likely to commit status offenses such as vandalism, running away, and other behaviors symbolic of their struggle for autonomy from parents. Life course–persistent offenders, in contrast, exhibit aberrant behavior in childhood, such as problems with temperament, behavioral development, and cognition, and as adolescents participate in more victim-oriented crimes. The public health model emphasizes the environment and other external influences. It focuses primarily on preventive strategies that view violence as amenable to systematic, science-based, multidisciplinary, and sustained interventions (Table 103–1). A third theoretical model examines violent behaviors across the spectrum occurring within and outside the family and is referred to as the cycle of violence. This hypothesis proposes that precursors such as child abuse and neglect, a child witnessing violence, adolescent sexual and physical abuse, and adolescent exposure to violence and violent assaults predispose youth to outcomes of violent behavior, violent crime, delinquency, violent assaults, suicide, or premature death. An additional common paradigm for high-risk violence behavior poses a balance of risk and protective factors at the individual, family, and community level. None of these theories successfully explains violent behavior. Although the media influences violence through a strong effect on aggressive behavior, many questions still remain about the causes of violent behavior.

Clinical Manifestations.

There are several clinical entities directly associated with violent behavior that require recognition and intervention. The most common behavioral diagnoses associated with aggressive behavior in adolescents are mental retardation, learning disabilities, moderately severe language disorders, and mental disorders such as attention-deficit/hyperactivity, mood disturbance, anxiety, and personality disorders. Inability to master prosocial skills such as the establishment and maintenance of positive family and peer relations and the resolution of conflict may put adolescents with these disorders at higher risk

TABLE 103-1 -- Public Health Approach to Youth Violence Prevention Model with Example

	Victim (Host)	Perpetrator (Vector)	Firearm (Agent)	Social Environment	Physical Environment
Primary prevention	Conflict resolution Violence anticipatory guidance	Substance abuse treatment Home visiting programs for new and single parents	Handgun and assault weapons ban Firearm registration	Job opportunities Adult-supervised activities	Better lighting Zoning-enforc limits in liquor licenses
Secondary prevention	Medical services Psychologic services	Job training Psychosocial rehabilitation	Handgun locks Public education on risks of ownership	School incident debriefing Safe havens	Increased pol presence Graffiti remov
Tertiary prevention	Physical rehabilitation Psychosocial services	Incarceration Educational-psychosocial rehabilitation	Firearm surveillance	Foster care Alternative schools	Urban plannir e.g., decrease population density in pub housing and mixture of income levels

From Calhoun AD, Clark-Jones F:Theoretical frameworks: Developmental psychopathology, the public health approach to violence, and the cycle of violence. Pediatr Clin North Am 1998; 45:287.

for physical violence and other risky behaviors. Conduct disorder and oppositional defiant disorder are specific psychiatric diagnoses whose definitions are associated with violent behavior (Table 103–2). They occur co-morbidly with other disorders such as attention-deficit/hyperactivity disorder and increase an adolescent's vulnerability for juvenile delinquency, substance use or abuse, sexual promiscuity, adult criminal behavior, incarceration, and antisocial personality disorder.

In an emergency or urgent care setting, one is very likely to encounter victims of physical and/or sexual assault. Rather than treat the physical injury in isolation, the American Academy of Pediatrics has established a model protocol for physical assault victims and guidelines for caring for sexual assault victims. The guidelines recommend psychologic evaluation and support, social service evaluation of the circumstance surrounding the assault, and a treatment plan on discharge that is designed to protect the adolescent from subsequent injury episodes and minimize the development of psychologic disability. Victims as well as witnesses of violence are at risk for post-traumatic stress disorder (see Chapter 22).

Diagnosis.

The assessment of an adolescent at risk for, or with a history of, violent behavior or victimization should be a part of the health maintenance visit of all adolescents. The answers to questions about recent history of involvement in a physical fight, carrying a weapon, or firearms in the household, as well as concerns that the adolescent may have about his or her personal safety may suggest a problem requiring a more in-depth evaluation. The additional factors of physical or sexual abuse, serious problems at school, poor school performance and attendance, multiple incidents of trauma, and symptoms associated with mental disorders are indications for evaluation by a mental

TABLE 103-2 -- **Oppositional Defiant Disorder, Conduct Disorder, and Juvenile Delinquency**

Psychiatric Disorder Labels		Legal Label
Oppositional Defiant Disorder	***Conduct Disorder***	***Juvenile Delinquency***
Recurrent pattern of negativistic, defiant, disobedient, and hostile behavior toward authority figures that have a significant adverse effect on functioning (e.g., social, academic, or occupational)	Repetitive and persistent pattern of behavior that violates the basic rights of others or major age-appropriate societal norms or rules	Offenses that are illegal because of age; illegal acts
Examples: losing temper; arguing with adults; defying or refusing to comply with request or rules of adults; annoying behavior; blaming others; and being irritable, spiteful, resentful	Examples: physical fighting, deceitfulness, stealing, destruction of property, threatening or causing physical harm to people or animals, driving without a license, prostitution, rape (even if not adjudicated in the legal system)	Examples: single or multiple instances of being arrested or adjudicated for any of the following: stealing, destruction of property, threatening or causing physical harm to people or animals, driving without a license, prostitution, rape
Diagnosed by a mental health clinician	Diagnosed by a mental health practitioner	Adjudicated in the legal system

From Greydanus DE, Pratt HD, Patel DR, Sloane MA: The rebellious adolescent. Pediatr Clin North Am 1997;44:1460.

health professional. In a situation of acute trauma, assault victims are not always forthcoming about the circumstances of their injuries for fear of retaliation or police involvement. Stabilization of the injury or the gathering of forensic evidence in sexual assault is the treatment priority; however, once this is achieved, addressing a more comprehensive set of issues surrounding the assault is appropriate.

Treatment.

In the instance of acute injury secondary to violent assault, the treatment plan should follow standards established by the American Academy of Pediatrics model protocol, which includes, but is not limited to, the stabilization of the injury, evaluation and treatment of the injury, evaluation of the assault circumstance, psychologic evaluation of the functioning of the victim, rehabilitation of the injury, and outpatient follow-up of the behavioral and physical sequelae. The American College of Emergency Physicians details the required examination and documentation for sexual assault victims in a handbook, *Evaluation and Management of Sexually Assaulted or Sexually Abused Patient.* Specific requirements for forensic evidence, as well as the management of sexually transmitted diseases and pregnancy prevention, are key elements of these recommendations. Specifically, prophylactic treatment of chlamydia and gonorrhea as well as postcoital contraception are recommended (see Chapters 208.2 , 177 , and 108).

Prevention.

Interventions to prevent violence must encompass individual and social factors. Violent behaviors are influenced not only by characteristics of individuals, but also by characteristics of families, such as cohesion and parent practices; characteristics of peers, such as delinquent behaviors; characteristics of schools, such as teacher practices and school atmosphere;

characteristics of community organization, such as the frequency and type of youth activities; and characteristics of the larger society, such as economic opportunity, misuse of firearms, or media exposure. Violence-prevention efforts to date have emphasized individually oriented strategies, directed toward students in school or patients in the clinical setting. These approaches should be continued, but need to be complemented by activities designed to modify exposures at the family, peer, community, and society level. **REFERENCES**

Chapter 104 - Anorexia Nervosa and Bulimia

Iris F. Litt

Epidemiology.

The incidence of anorexia nervosa (AN) and bulimia (BN) has increased over the last 2 decades. It is estimated that 1 in every 100 females, 16–18 yr old, has anorexia nervosa. A bimodal distribution occurs, with one peak at 14.5 and the other at 18 yr; 25% may be younger than the age of 13. The increased incidence has been documented in all Western countries, with sporadic reports from other nations. Affected females outnumber males 10:1. Initially reported only in middle and upper socioeconomic groups, AN is now occurring in those from the lower socioeconomic levels and in a variety of ethnic and racial groups. BN is more common than AN. An increased incidence of eating disorders among primary relatives of those with AN and BN suggests a familial basis.

Diagnosis.

The *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)* criteria for the diagnosis of AN include (1) intense fear of becoming obese, which does not diminish as weight loss progresses; (2) disturbance in the way in which one's body weight, size, or shape is experienced (e.g., claiming to “feel fat” even when one is emaciated or believing that one area of the body is “too fat” even when obviously underweight); (3) refusal to maintain body weight over a minimal normal weight for age and height (e.g., weight loss leading to maintenance of body weight 15% below expected, failure to make expected weight gain during period of growth leading to body weight 15% less than that expected); and (4) in females, absence of at least three consecutive menstrual cycles when otherwise expected to occur (primary or secondary amenorrhea).

AN is characterized further by excessive physical activity in the face of apparent inanition; denial of hunger; preoccupation with food preparation, frequently accompanied by bizarre eating behaviors; and often studiousness and academic success. Many are described as having been “model children” before the onset of the illness. Patients who have AN are subdivided into the *restrictor* and *BN* subgroups, according to their method of caloric reduction. Restrictors severely limit their intake of carbohydrate and fat-containing foods, whereas bulimics tend to eat in binges and then to purge themselves of food by self-induced vomiting or the use of

cathartics. Excoriations on the dorsum of the hand from self-induced vomiting may suggest the diagnosis.

DSM-IV separates *BN* from AN as a diagnostic entity, defining BN as (1) recurrent episodes of binge eating (rapid consumption of a large amount of food in a discrete period of time, usually less than 2?hr); (2) during the eating binges, a fear of not being able to stop eating; (3) regularly engaging in self-induced vomiting, use of laxatives, or rigorous dieting or fasting in order to counteract the effects of binge eating; (4) a minimum average of two binge eating episodes per week for at least 3 mo; and (5) self-evaluation is unduly influenced by body weight and shape, but the disturbance does not occur exclusively during episodes of AN. The binge-purge pattern may occur in youngsters who have normal weight or are slightly obese.

Etiology and Psychodynamics.

Eating disorders commonly begin as innocent dieting behavior, not unlike that seen in many other adolescent women, but those with AN gradually progress to profound weight loss with emaciation. Premorbid psychiatric characteristics of patients with AN may include excessive dependency, developmental immaturity, and isolation. Their families have been described as having difficulty with problem solving and as being intrusive and overprotective. The onset of these conditions at the time of puberty has prompted psychoanalysts to regard them as defenses against emerging sexuality, an opinion that dominated thinking until the 1950s, when Bruch conceptualized AN as a problem in identity development. Others consider that AN may represent a disorder of mood accompanied by manic or depressive symptoms. Patients with AN have also been subcategorized on the basis of psychologic characteristics in order to demonstrate that different subgroups are dynamically and prognostically different. Biogenic amine neurotransmitter abnormalities are found in some patients with AN. Their etiologic significance is unclear.

Clinical Manifestations.

AN and BN are associated with disturbances in almost every organ system, although it is uncertain which may be primary and which is the result of severe malnutrition. The death rate in AN is approximately 10% and is usually caused by severe electrolyte disturbance, cardiac arrhythmia, or congestive heart failure in the recovery phase. *Bradycardia* and *postural hypotension* are common, with pulse rates as low as 20 beats/min. Both improve with nutritional therapy. A variety of electrocardiographic abnormalities is common, including low voltage, T-wave inversion and flattening, and ST depression, as well as supraventricular and ventricular dysrhythmias, some preceded by a prolonged QT_c interval. Decreased cardiac output and mitral valve prolapse may result from myofibrillar atrophy. Patients who have abused ipecac may develop myocarditis. Death from congestive heart failure is a late event and may result from unduly rapid rehydration and refeeding. On a regimen achieving a daily weight gain limited to 0.2–0.4 kg, none of our patients has experienced this complication. Other manifestations of the “refeeding syndrome” include hypophosphatemia as a result of insulin-induced shifts of phosphate to intracellular space.

Sleep disturbances occur in some patients with AN and include a short rapid eye movement latency time, similar to that

---

often found in depressed patients. Problems of thermal regulation, particularly hypothermia, are common (15% of our patients had temperatures recorded below 35°C). Hypothermia also occurs in bulimics of normal weight.

Disorders of the hypothalamic-pituitary-ovarian axis are manifested as amenorrhea associated with immature patterns of secretion of luteinizing hormone. These findings may represent a primary hypothalamic defect rather than being secondary to weight loss (which also causes amenorrhea), inasmuch as amenorrhea antedates weight loss in one third to one half of patients with AN, and a similar proportion fail to resume menses when normal weight is restored. One quarter of patients may be amenorrheic for ten or more years, despite weight rehabilitation. Evidence for hypothalamic-pituitary-adrenal axis dysfunction includes increased secretion of cortisol, loss of diurnal variation in its secretion, and failure of dexamethasone to suppress it. The last may also be found in starvation; however, in 44% of our patients with AN, abnormal results of dexamethasone suppression tests have persisted after weight rehabilitation. Growth hormone secretion is abnormally high in these patients, and somatomedin-C is low. Thyroid-stimulating hormone levels are normal, thyroxine and triiodothyronine are low, and reverse triiodothyronine is elevated, presumably in adaptation to a lowered basal metabolic rate as a result of malnutrition and carbohydrate deprivation. In some patients, peripheral edema in the absence of congestive heart failure or hypoproteinemia has been attributed to inappropriate secretion of antidiuretic hormone.

Elevations of blood urea nitrogen level may occur, reflecting dehydration and decreased glomerular filtration rate, but normal levels may be found under these same conditions because of low protein intake even in the dehydrated patient. Mild proteinuria, hematuria, and pyuria, with negative urine cultures, generally resolve with proper rehydration. Pseudoproteinuria is often found because the alkalinity of the urine gives a false-positive reaction to albumin on the dipstick.

Neuropsychologic effects of AN include impairment of concentration and problem solving, as well as attentional-perceptual and motor function. Structural changes occur in the brain, such as deficits in volume of white and gray matter, the latter persisting after weight rehabilitation.

Bone marrow hypoplasia is common in AN, with leukopenia, anemia, and (rarely) thrombocytopenia. Low erythrocyte sedimentation rates are also common, perhaps reflecting low fibrinogen production secondary to malnutrition.

Constipation is a common complication of motility problems in AN, as is esophagitis in those who vomit. Decreased gastrointestinal tract motility may be a cause of perforation following nasogastric tube insertion. Elevations in amylase levels may be associated with bilateral parotid swelling or with pancreatitis.

Electrolyte imbalance (in addition to hypophosphatemia in refeeding) results from vomiting, “waterloading” (a practice of surreptitiously drinking large amounts of water

in order to achieve an agreed-upon weight gain), or abuse of diuretics or laxatives. Potassium depletion, associated with a hypochloremic alkalosis, is common. Abnormalities of calcium, magnesium, and phosphorus metabolism may result from laxative abuse, either secondary to malabsorption or resulting from the use of preparations containing phosphate. Paradoxically, cholesterol levels are often elevated in AN.

Patients with AN appear to be remarkably resistant to infection, and the few studies of their immunologic status support this view. The fact that protein intake is relatively good in these otherwise malnourished persons may contribute to this finding. Bone density may be abnormally low with the associated risk of stress fractures, but this osteopenia appears to improve with weight gain. A number of possible mechanisms have been suggested to explain this finding, including low levels of estrogen and calcium and elevated cortisol levels. The skin of patients with AN is dry, and lanugo hair is often seen. Hair loss often occurs in the refeeding phase.

Treatment.

Systematic, controlled studies of treatment in these disorders are not available. Most of the regimens in current use combine psychotherapy (individual and family), behavior modification techniques, and nutritional rehabilitation. Pharmacologic therapy (primarily with antidepressant medications) appears to be helpful for that subset of depressed patients with eating disorders. The success rate in short-term follow-up studies is about 70%. The frequent occurrence of medical complications and the possibility of death during the acute or rehabilitation phase require the inclusion of a medically and physiologically oriented physician in the management team.

Chapter 105 - Substance Abuse

Renée R. Jenkins

Cultural and societal norms frame acceptable standards for substance use. These standards also have a historical context. Adolescents are influenced by adult role models and environmental messages related to substances. For example, children of alcoholic parents are 2 to 10 times more likely to develop alcoholism than children of nonalcoholic parents. In the context of the current decade, occasional or situational use of certain substances such as alcohol, marijuana, and cigarettes may be viewed as “normative” given the proportion of youth who report some experience with these substances. Some studies suggest that otherwise normal, healthy, adolescents who “experiment” with drugs may be better adjusted than those who lack that experience. Others view the potential for adverse outcomes even with occasional use in immature adolescents, such as motor vehicle accidents and other injuries, sufficient justification to consider any drug use in younger adolescents a considerable risk.

The developmental considerations are probably most important for this age group. Substance use for most teenagers is not an issue of psychopathology but of the influence on normal functioning. Drug use in younger, less experienced adolescents can act as a substitute for developing age-appropriate coping strategies and enhance vulnerability to poor decision-making. Early adolescent use is also associated with greater vulnerability to adult addictions. When drug use begins to negatively alter functioning in older adolescents at school and in the family, and risk-taking behavior is seen, intervention is warranted. Serious drug use is not an isolated phenomenon. It is a part of a complex set of family and individual issues that should be addressed in a comprehensive fashion. The challenge to the clinician is to determine which type of behavior one is observing and to take the necessary action. The challenge to the community and society is to create norms that decrease the likelihood of adverse health outcomes for adolescents and promote and facilitate opportunities for adolescents to choose healthier and safer options for experimentation.

Etiology.

The determinants of adolescent substance use and abuse have been explained using a number of theoretical models. Most of the models include factors at the individual level, the level of significant relationships with others, and the level of

the setting, that is, community or other environment. Models have also begun to include a balance of risk and protective or coping factors that tend to account for individual differences among adolescents with similar risk factors who escape adverse outcomes. Duncan and Petrosa also argue for differentiating the risk factors for adolescent use compared with adolescent abuse. Adolescent use is more commonly related to social and peer factors, whereas abuse is more often a function of psychologic and biologic factors. The likelihood that an otherwise normal adolescent would experiment with drugs may be dependent on the availability of the drug to the adolescent, the perceived positive or otherwise functional value to the adolescent, and the presence or absence of restraints as determined by the adolescent's cultural or other important value systems. An abusing adolescent, in contrast, may have genetic or biologic factors coexisting with dependence on a particular drug for coping with day-to-day activities. In addition, such an adolescent may adopt an identification with the addicted role, with a fear of the consequences of withdrawal.

Specific historical questions can assist in determining the severity of the drug problem through a rating system as depicted in Table 105–1 . The type of drug used (e.g., marijuana versus heroin), the circumstances of use (e.g., alone or in a group setting), the frequency and timing of use (e.g., daily before school versus rarely on a weekend), the premorbid personality (depressed versus happy), as well as the teenager's general functional status should all be considered in evaluating any youngster found to be abusing a drug. In addition, certain protective factors play a part in buffering the risk factors as well as assisting in anticipating the long-term outcome of experimentation. Emotionally supportive parents with open communication styles, involvement in organized school activities, and recognition of the importance of academic achievement are a few of the important protective factors. Involvement in organized sports activities is usually protective, but it may be a risk factor in regard to the use of anabolic steroids. Any use of a psychoactive drug in the context of the use of machinery or a motor vehicle or in a potentially volatile interpersonal interaction can add an increased health risk, regardless of the extent of any prior use.

Epidemiology.

Surveys on adolescent substance use have a variety of limitations due to sampling and questionnaire differences. The National Household Survey on Drug Abuse may reflect refusal to report use within a household. School-based surveys (Monitoring the Future study and Youth Risk Behavior Surveillance) do not capture school dropouts, school absenteeism, and high rates of refusal. The rates of drug use across surveys is not dramatically different and certain observations are consistent across surveys. Alcohol and cigarettes are the most prevalent drugs (Table 105–2). Marijuana tends to be the most commonly reported illicit

TABLE 105-1 -- **Assessing the Seriousness of Adolescent Drug Abuse**

Variable	0	+1	+2
Age (yr)	>15 yr	<15 yr	
Sex	Male	Female	
Family history of drug abuse		Yes	
Setting of drug use	In group		Alone
Affect before drug use	Happy	Always poor	Sad
School performance	Good, improving		Recently poor
Use before driving	None		Yes
History of accidents	None		Yes
Time of week	Weekend	Weekdays	
Time of day		After school	Before school
Type of drug	Marijuana, beer, wine	Hallucinogens, amphetamines	Whiskey, opiates, cocaine, barbiturates
Total score: 0–3 less worrisome, 3–8 serious, 8–18 very serious.			

TABLE 105-2 -- **Lifetime Use of Cigarettes, Alcohol, Marijuana, MDMA, and Steroids (Anabolic-Androgenic) in 8th, 10th, and 12th Grades, 1997 and 2001**

		8th Grade (%)	10th Grade (%)	12th Grade (%)
Cigarettes	1997	47.3	60.2	65.4
	2001	36.6	52.8	61.0
Alcohol	1997	53.8	72.0	81.7
	2001	50.5	70.1	79.7
Marijuana	1997	22.6	42.3	49.6
	2001	20.4	40.1	49.0

MDMA (Ecstasy)	1997	3.2	5.7	6.9
	2001	5.2	8.0	11.7
Steroids (anabolic)	1997	1.8	2.0	2.4
Steroids (anabolic)	2001	2.8	3.5	3.7

From Johnston LD, O'Malley PM, Bachman JG: High School and Youth Trends: 2001 Monitoring the Future Study (MTF), NIDA. U.S. Department of Health and Human Services (www.drugabuse.gov/Infofax/HSYouthtrends.html), accessed 2/24/02.

drug ever used. The prevalence of substance use varies by age, gender, geographic region, race, and other demographic factors. Younger teenagers tend to report less use of most drugs than do older teenagers, with the exception of inhalants (17.1% in 8th grade, 15.2% in 10th grade, and 13.0% in 12th grade, 2001). Males strongly predominate in the lifetime prevalence reports for smokeless tobacco and anabolic steroids compared with females. Marijuana use is reported more frequently in large metropolitan areas, whereas less urbanized areas report more binge drinking and daily cigarette use. In school surveys, Hispanics report more experience with cocaine, whereas white students report high rates of smokeless tobacco and daily cigarette smoking. By 12th grade, blacks report less use of drugs across all categories.

In examining trends in drug use, fewer students reported marijuana, alcohol, and cigarette use over the years since 1997 in 8th, 10th, and 12th grades, with 8th graders showing the greatest declines (see Table 105–2). Alarming trends are seen in MDMA (Ecstasy) and anabolic steroid use, increasing across all grades since 1997.

Pathogenesis.

The process of physical growth and development that characterizes puberty may be affected adversely by the use of drugs. For example, one third of adolescent females who use *heroin* have secondary amenorrhea, even in the absence of weight loss. The higher incidence of menstrual abnormalities in the adolescent heroin user probably results from a greater vulnerability of the hypothalamic-pituitary-ovarian axis in the maturing individual. Experiments with naloxone, the opiate antagonist, suggest that endogenous opiates block the release of gonadotropin-releasing hormone. *Amphetamines* interfere with stage 4 sleep and may impair the intimate relationship between sleep and augmentation of secretion of gonadotropin during early adolescence (also see Chapter 20.5). To derive calories mainly from *ethanol* during the peak of the pubertal growth spurt deprives the body of the protein necessary for normal muscle growth.

The metabolism of certain prescribed drugs may be affected by coincident abuse of illicit drugs or alcohol. Induction of hepatic smooth endoplasmic reticulum by barbiturates or alcohol may accelerate the metabolism and enhance the excretion of substances requiring glucuronidation. As a result of this mechanism, estrogen-containing oral contraceptives taken by an abuser of these substances may result in a vulnerability to pregnancy. Conversely, the use of estrogens increases the risk of intoxication from alcohol as a result of decreased ethanol metabolism. The potentiating interaction of alcohol and barbiturates must also be considered when prescribing anticonvulsant medications. Abdominal pain and vomiting occur when metronidazole is ingested by an alcohol-abusing adolescent because of the antagonistic effect of alcohol on acetaldehyde.

Clinical Manifestations.

Although manifestations vary by the specific substance of use, adolescents who use drugs often present in an office setting with no obvious physical findings. Drug use is more frequently detected in adolescents who are victims of motor vehicle accidents or intentional injuries. Eliciting appropriate historical information regarding substance use followed by a blood alcohol and a urine drug screen is recommended in emergency settings. In addition, an adolescent presenting to an emergency setting with an impaired sensorium as part of a toxic syndrome should be evaluated for substance use as a part of the differential diagnosis, again accompanied by appropriate screening and physical examination (Box 105–1). Certain psychiatric and behavioral diagnoses are frequently associated with substance use and should be considered once such use is detected. Conversely, screening for substance use is recommended for patients with psychiatric and behavioral diagnoses. Diagnoses that are commonly considered range from conduct disorders, with or without attention deficit disorder, to personality disorders. Other clinical manifestations of substance use are associated with the route of use; intravenous drug use is associated with venous “tracks” and needle marks, and nasal mucosal injuries are associated with nasal insufflation of drugs. Seizures can be a direct effect of drugs such as cocaine and amphetamines or an effect of drug withdrawal in the case of barbiturates or tranquilizers. Additional specific clinical manifestations are described in the following sections on each substance.

Screening for Substance Abuse and Use.

The annual health maintenance examination provides an opportunity for identifying adolescents with substance use or abuse issues (see Chapters 17 and 100). The direct questions as well as the assessment of school, family relations, and peer activities may necessitate a more in-depth interview if there are suggestions of difficulties in those areas. Several self-report screening questionnaires are available with varying degrees of standardization, length, and reliability. The classic CAGE mnemonic used for screening

adults for alcohol abuse has been modified for use in adolescents and new mnemonics specifically designed for adolescents are in use, e.g., CRAFFT (Box 105–2) and RAFFT. The use of urine screening is recommended in select circumstances, most of which are constructed to provide for the confidentiality and informed choice of the adolescent. Involuntary screening with parental permission is strongly discouraged for older, competent adolescents. Lack of decision-making capacity or very strong medical indications may present a clinical situation in which consent may be waived. Indications for urine screening include (1) psychiatric symptoms, to rule out co-morbidity or dual diagnoses; (2) significant changes in school performance or other daily behaviors; (3) frequently occurring accidents; (4) frequently occurring episodes of respiratory problems; (5) evaluation of serious motor vehicular of other injuries; and (6) as a monitoring procedure for a recovery program. Table 105–3 demonstrates the types of tests commonly used for detection by substance, along with the approximate retention time between the use and the identification of the substance in the urine. Most initial screening uses an immunoassay method such as the enzyme-multiplied immunoassay technique followed by a confirmatory test using the highly sensitive, highly specific gas chromatography-mass spectrometry. The substances that can cause false-positive results should be considered, especially when there is a discrepancy between the physical findings and the urine drug screen result.

Diagnosis.

Diagnostic criteria that classify the severity of substance use-abuse range from substance use variation, through the diagnosis of a substance abuse problem, to the definition of a substance abuse disorder. Substance abuse variation refers to the experimentation that commonly occurs in this age group. An adolescent is considered to have a diagnosis of a substance abuse problem if the use occurs more than on a one-time basis and involves impaired memory or other motor function deficits. A substance abuse disorder is diagnosed when there is impaired

functioning in key settings such as in school, at home, and with peers. The criteria for a disorder encompasses the issues of tolerance, frequency or volume of drug taken, period of time of use, inability to stop the use, and amount of time consumed by drug activities relative to normal activities. Specific diagnostic codes are assigned to substance abuse, substance intoxication, and substance withdrawal. The stages of the progression from substance use to dependence are depicted in Box 105–3 . Referral to a specialist in or program for substance abuse treatment should occur by stage 3, unless the primary care physician has additional knowledge or training in addiction medicine.

Complications.

Substance use in adolescence has psychologic as well as physical risks. Youth may engage in robbery, burglary, drug dealing, or prostitution for the purpose of acquiring the money necessary to buy drugs or alcohol. Regular use of any drug eventually diminishes judgment and is associated with unprotected sexual activity with its consequences of pregnancy and sexually transmitted diseases, including human immunodeficiency virus (HIV), as well as physical violence and trauma. Drug and alcohol use are closely associated with trauma in the adolescent population. Several studies of adolescent trauma victims have identified cannabinoids and cocaine in blood and urine samples in significant proportions, in addition to the more common

identification of alcohol. Any use of injected substances involves the risk of hepatitis and HIV.

TABLE 105-3 -- Urine Screening for Drugs Commonly Abused by Adolescents

Drug	Major Metabolite	Initial	First Confirmation	Second Confirmation	Approximate Retention Time
Alcohol (blood)	Acetaldehyde	GC	IA		7–10 hr
Alcohol (urine)	Acetaldehyde	GC	IA		10–13 hr
Amphetamines		TLC	IA	GC,GC/MS	48 hr
Barbiturates		IA	TLC	GC,GC/MS	Short-acting (24 hr); long-acting (2–3 wk)
Benzodiazepines		IA	TLC	GC,GC/MS	3 days
Cannabinoids	Carboxy- and hydroxymetabolites	IA	TLC	GC/MS	3–10 days (occasional user); 1–2 mo (chronic user)
Cocaine	Benzoyl ecgonine	IA	TLC	GC/MS	2–4 days
Methaqualone	Hydroxylated metabolites	TLC	IA	GC/MS	2 wk
Opiates					
Heroin	Morphine Glucuronide	IA	TLC	GC,GC/MS	2 days
Morphine	Morphine Glucuronide	IA	TLC	GC,GC/MS	2 days
Codeine	Morphine Glucuronide	IA	TLC	GC,GC/MS	2 days
Phencyclidine		TLC	IA	GC,GC/MS	8 days

Box 105-3. Stages of Adolescent Substance Abuse

STAGE	DESCRIPTION
1	Potential for abuse • Decreased impulse control • Need for immediate gratification • Available drugs, alcohol, inhalants • Need for peer acceptance
2	Experimentation: learning the euphoria • Use of inhalants, tobacco, marijuana, and alcohol with friends • Few, if any, consequences • Use may increase to weekends regularly • Little change in behavior
3	Regular use: seeking the euphoria • Use of other drugs, e.g., stimulants, LSD, sedatives • Behavioral changes and some consequences • Increased frequency of use; use alone • Buying or stealing drugs
4	Regular use: preoccupation with the “high” • Daily use of

4	Regular use: preoccupation with the "high" • Daily use of drugs • Loss of control • Multiple consequences and risk-taking • Estrangement from family and "straight" friends
5	Burnout: use of drugs to feel normal • Poly substance use/cross-addiction • Guilt, withdrawal, shame, remorse, depression • Physical and mental deterioration • Increased risk-taking, self-destructive, suicidal

From Comerci GD: Recognizing the five stages of substance abuse. Contemp Pediatr 1985;2:57–68.

Prevention.

The model of prevention relevant to the problem of adolescent drug or alcohol use is one that anticipates experimentation with some agent at some point in the normal development of the adolescent and that attempts to delay that event as long as possible, to make its use as limited in amount and setting as possible, and to prevent entirely any use while operating a motor vehicle or any other machinery. The Center for Substance Abuse Prevention has identified 6 program characteristics that have produced statistically significant reduction in 30-day substance use for adolescents: (1) Life Skills Focus—promoting attitudinal and behavioral life skills; (2) Emphasis on Building Connectedness—emphasizing connectedness to positive peers

and adults; (3) Coherent Program Design and Implementation—linking activities to articulated and coherent prevention theory; (4) Introspective Orientation—encouraging youth to examine their own attitudes and behaviors and their contextual impact; (5) Intensive Contact—4 or more contact hours per week; and (6) After-school Setting—as compared to classroom delivery. Programs that delivered at least 5 of the 6 characteristics demonstrated strong prevention benefits through an 18-month follow-up period.

Treatment.

Acute management is discussed in the following sections on specific agents. A variety of chronic treatment programs are available in inpatient and ambulatory settings. Brief interventions, including motivational interviewing, have been used in alcohol and tobacco users with some clinical effectiveness. These interventions are time-limited and patient-centered, with clear advice provided; they are useful in the primary care setting. Important features of successful long-term management of these adolescents include continuing medical evaluation after detoxification and the provision of developmentally appropriate psychosocial support systems.

Prognosis.

For adolescent substance abusers who have been referred to a drug treatment program, outcomes are directly related to regular attendance in post-treatment groups. For males with learning problems, these outcomes were worse than were those of their peers without learning problems. Peer use patterns and parental use have a major influence on outcome for males. For females, factors such as self-esteem and anxiety are more important influences on outcomes. The chronicity of a substance abuse disorder makes relapse an issue that must always be kept in mind when managing patients after treatment, and appropriate assistance from a health professional qualified in substance abuse management should be obtained.

105.2 Alcohol

Alcohol use among adolescents has increased during the past decade and poses a threat to the normal functioning of the teenager as well as to the lives of those potentially jeopardized by drunken drivers. The initiation of alcohol use at an early age is associated with an increased risk for alcohol-related problems unless moderate use is deeply rooted in the adolescent's cultural tradition. The usual progression of alcohol use is from beer to wine to hard liquor, although regional differences may alter this pattern. Four ounces of hard liquor (86 proof) consumed on an empty stomach produces a plasma ethanol level of approximately 65?mg/dL in an adult male of average weight and 80?mg/dL in a premenstrual female of adult weight. The legal definition of intoxication in most statutes is a blood ethanol level of 80 or 100?mg/dL (0.08% or 0.10%).

Alcohol is noted as a contributing factor in 8,000 adolescent deaths and 45,000 injuries each year. Approximately 40% of the 10,000 annual nonautomotive accidental deaths, such as drowning and falls, are also associated with alcohol use. The estimates for involvement in suicide and homicide reach about 5,000/diagnosis/year. For a legal drug, alcohol contributes to more deaths in young individuals than all the illicit drugs combined. Therefore, pediatricians should not underestimate the need to recognize alcohol use and abuse in this age group.

Pharmacology and Pathophysiology.

Alcohol (ethyl alcohol or ethanol) is rapidly absorbed in the stomach and is transported to the liver and metabolized by two pathways. The primary pathway involves removal of two hydrogen atoms to form acetaldehyde, a reaction catalyzed by alcohol dehydrogenase through reduction of a cofactor nicotinamide-adenine dinucleotide. The removed hydrogen atoms supply energy (7.1?kcal/g of alcohol) and contribute to the excess synthesis of triglycerides, a phenomenon that is responsible for producing a fatty liver, even in those who are well nourished. Engorgement of hepatocytes with fat causes necrosis, triggering an inflammatory process (alcoholic hepatitis), which is followed by fibrosis, the hallmark of cirrhosis. Early hepatic involvement may result in elevation in ?-glutamyl transpeptidase and serum glutamic-pyruvic transaminase. The second metabolic pathway, which is utilized at high serum alcohol levels, involves the microsomal system of the liver, in which the cofactor is reduced nicotinamide-adenine dinucleotide phosphate. The net effect of activation of this pathway is to decrease metabolism of drugs that share this system and to allow for their accumulation, enhanced effect, and possible toxicity (e.g., drinking alcohol and ingesting tranquilizers results in the potentiation of each).

Clinical Manifestations.

Alcohol acts primarily as a central nervous system (CNS) depressant. It produces euphoria, grogginess, talkativeness, and impaired short-term memory, and it increases the pain threshold. Alcohol's ability to produce vasodilation and hypothermia is also centrally mediated. At very high serum levels, respiratory depression occurs. Its inhibitory effect on pituitary antidiuretic hormone release is responsible for its diuretic effect. The gastrointestinal complications of alcohol use can occur from a single large ingestion. The most common is acute erosive gastritis, which is manifested by epigastric pain, anorexia, vomiting, and guaiac-positive stools. Less commonly, vomiting and midabdominal pain may be caused by acute alcoholic pancreatitis; diagnosis is confirmed by the finding of elevated serum amylase and lipase activities.

Only a small number of adolescents become young alcoholics; however, problem drinking during adolescence requiring a therapeutic intervention is not uncommon. Adolescents who report having been drunk six or more times in the past year; having problems with school authorities, friends, or the police; having been criticized by dates for drinking habits; or having driven after drinking are considered problem drinkers.

Diagnosis.

In addition to the general risk factors noted for substance use, a positive family history of alcohol abuse is significant. The genetic influences for the predisposition to alcoholism are supported by family, twin, and adoption studies. Children of alcoholic parents demonstrate a three- to fourfold increase in the risk for alcoholism. The *alcohol overdose syndrome* should be suspected in any teenager who appears disoriented, lethargic, or comatose (see Box 105–1). Although the distinctive aroma of alcohol may assist in diagnosis, confirmation by analysis of blood is recommended. There is a high correlation between results obtained by serum and breath analyses so that the latter method may be reliably used. At levels greater than 200?mg/dL, the adolescent is at risk of death, and levels greater than 500?mg/dL (median lethal dose) are usually associated with a fatal outcome. When the level of depression appears excessive for the reported blood level, head trauma or ingestion of other drugs should be considered as possible confounding factors.

Treatment.

The usual mechanism of death from the alcohol overdose syndrome is respiratory depression, and artificial ventilatory support must be provided until the liver can eliminate sufficient amounts of alcohol from the body. In a patient without alcoholism, it generally takes 20?hr to reduce the blood level of alcohol from 400?mg/dL to zero. Dialysis should be considered when the blood level is higher than 400?mg/dL.

105.3 Marijuana

Marijuana and alcohol, the most popular substances of abuse among adolescents, share a number of psychopharmacologic qualities. Both decrease short-term memory and fine coordination, prolong reaction time, and produce “mental clouding.” About 300?mg of cannabis is equivalent to 70?g of alcohol.

Pharmacology.

Marijuana (THC, “pot,” “weed,” “hash,” “grass”) is synthesized from the resin of the *Cannabis sativa* plant, which flourishes in temperate and hot, dry climates. The tetrahydrocannabinol (THC) fraction of the resin is responsible for its hallucinogenic properties and has been synthesized (d-9-THC). THC is absorbed rapidly by the nasal or oral routes, producing a peak of subjective effect at 10?min and 1?hr, respectively. Marijuana is generally consumed as a “reefer” or “joint,” made by rolling the crushed plant material in paper. Although there is much variation in content, each cigarette contains 8–10% THC. Another popular form that is smoked, a “blunt,” is a hollowed-out small cigar refilled with marijuana.

Clinical Manifestations.

In addition to the “desired” effects of elation and euphoria, marijuana may cause impairment of short-term memory, poor performance of tasks requiring divided attention (e.g., those involved in driving), loss of critical judgment, and distortion of time perception. Visual hallucinations and perceived body distortions occur rarely, but there may be “flashbacks” or recall of frightening hallucinations experienced under marijuana's influence that usually occur during stress or with fever.

Temperature may be lowered. Tachycardia is apparent within 20?min of smoking marijuana and is followed ½?hr later by transient systolic and diastolic hypertension, which disappears by 3?hr. Heavy users report pharyngitis, sinusitis, bronchitis, and asthma. In placebo-controlled studies of experienced users, smoking marijuana caused hypercapnic ventilation and a decrease in forced expired volume, maximal midexpiratory flow rate, airway conductance, and diffusing capacity. Both d-9-THC and marijuana (smoking a single joint) cause a significant fall in intraocular pressure, lasting up to 5?hr in normal persons as well as in patients with glaucoma.

Kolodny demonstrated dose-related suppression of plasma testosterone levels and

spermatogenesis as a result of smoking marijuana for a minimum of 4 days/wk for 6 mo, prompting concern about the potential deleterious effect of smoking marijuana before completion of pubertal growth and development. There is an antiemetic effect of oral THC or smoked marijuana, often followed by appetite stimulation, which is the basis of the drug's use in patients receiving cancer chemotherapy. Although the possibility of teratogenicity has been raised because of findings in animals, there is no evidence for such effects in humans. An “amotivational” syndrome has been described in chronic marijuana users who lose interest in age-appropriate behavior, yet proof of the causative relationship remains equivocal. The increased THC content of marijuana of almost 5 to 15 times in the 1990s as compared to the 1970s is related to the observation of a withdrawal syndrome, which had not occurred in the past, occurring 24 to 48?hr after discontinuing the drug. Heavy users experience malaise, irritability, agitation, insomnia, drug craving, shakiness, diaphoresis, night sweats, and gastrointestinal disturbance. The symptoms peak by the fourth day and resolve in 10 to 14 days. Certain drugs may interact with marijuana to potentiate sedation (i.e., alcohol, diazepam), potentiate stimulation (i.e., cocaine, amphetamines), or be antagonistic (i.e., propranolol, phenytoin). Long-term heavy cannabis users show memory and attention impairments that last beyond the period of intoxication and worsen with increasing years of regular use.

105.4 Tobacco

CIGARETTES

The average smoker starts at age 12 yr, and most are regular smokers by age 14 yr. Most alarming is the compelling evidence of the addictive nature of cigarette smoking with greater than 90% of adolescent smokers becoming adult smokers. Compared with all other substances and firearms, tobacco kills more individuals in the United States each year than all these other causes combined. The severity of atherosclerosis may be correlated with the duration of smoking, increasing its risk among those who begin smoking during adolescence.

Pharmacology.

Human and animal studies confirm the addictive effect of nicotine, the primary active ingredient in cigarettes. It produces a syndrome of dependence as well as withdrawal. Nicotine is absorbed by multiple sites in the body, including lungs, skin, gastrointestinal tract, and buccal and nasal mucosa. The average nicotine content of one cigarette is 10?mg and the average nicotine intake per cigarette ranges from 1.0?mg to 3?mg. Nicotine, as delivered in cigarette smoke, has a half-life of 10–20?min, with an elimination half-life of 2–3?hr. Nicotine's effect on the brain takes less than 20?sec. The action of nicotine is mediated through nicotinic acetylcholine receptors. These receptors are located on noncholinergic presynaptic and postsynaptic sites in the brain. Cotinine is the major metabolite of nicotine via C-oxidation. It has a biologic half-life of 19–24?hr and can be detected in urine, serum, and saliva.

Clinical Manifestations.

Adverse health effects of smoking may occur during adolescence. These adverse effects include an increased prevalence of chronic cough, phlegm production, and wheezing. Smoking during pregnancy is associated with an average decrease in fetal weight of 200?g; this, added to the already smaller size of infants born to teenagers, increases perinatal morbidity and mortality. Smoking in combination with the use of estrogen-containing oral contraceptives is associated with an increased risk of myocardial infarction. Tobacco smoke induces hepatic smooth endoplasmic reticulum and, as a result, may also influence metabolism of drugs and of endogenously produced hormones. Phenacetin, theophylline, and imipramine are examples of drugs affected in this manner. In addition, laboratory test results may be affected by smoking, for example, white blood cell count, hemoglobin, hematocrit, mean corpuscular volume, and platelet aggregation are increased and serum creatinine, albumin, globulin (in females), and uric acid (in males) are decreased

(see Chapter 710).

Treatment.

The approach to smoking cessation in adolescents includes the use of nicotine replacement therapy in addicted teens who are motivated to quit and are not using smokeless tobacco (SLT). The nicotine patch method, available over the counter or by prescription, is the most useful form in this age group; however, gum and spray can also be used. Medications such as bupropion, clonidine, and nortriptyline can be considered if nicotine replacement is ineffective or inappropriate. Additional options may be available through formal smoking cessation programs offered by community agencies. Clinical practice guidelines are available for practical office-based counseling strategies. Health supervision and supportive counseling are necessary components to smoking cessation management in adolescents.

SMOKELESS TOBACCO

Surveys in the late 1980s and 1990s indicating the increased use of smokeless tobacco (SLT) prompted the National Cancer Institute to lead the United States' federal government effort to prevent SLT use, especially in adolescents. Surveys now indicate that since the early to mid-1990s, lifetime prevalence of SLT use has declined in 8th, 10th, and 12th graders. Regular users of SLT risk physical dependence on nicotine. Chewing tobacco may result in lesions, primarily in the mandibular mucobuccal fold. With chronic use, these lesions may become malignant.

105.5 Volatile Substances

The practice of inhalation of a variety of euphoriants has enjoyed popularity among adolescents for centuries. The first

well-described documentation of this phenomenon related to an “epidemic” of ether sniffing by Irish teenagers in the 19th century. Young adolescents are attracted to these substances because of their rapid action, easy availability, and low cost. The most popular inhalants among adolescent are glue, gasoline, and volatile nitrites. “Huffing,” directly inhaling, or inhaling deeply from a paper bag containing a chemical-soaked cloth is the common method used by teens.

Clinical Manifestations.

The major effects of inhalants are psychoactive. Toluene, the main ingredient in airplane glue and some rubber cements, causes relaxation and pleasant hallucinations for up to 2?hr. Tolerance and physical dependence may occur. Gasoline, a popular substance among rural adolescents and Native American youth, contains a complex mixture of organic solvents. Euphoria is followed by violent excitement, and coma may result from prolonged or rapid inhalation. Volatile nitrites, such as amyl nitrite, butyl nitrite, and related compounds marketed as room deodorizers, are used as euphoriants, enhancers of musical appreciation, and aphrodisiacs among older adolescents and young adults. They may result in headaches, syncope, and lightheadedness; profound hypotension and cutaneous flushing followed by vasoconstriction and tachycardia; transiently inverted T waves and depressed ST segments on electrocardiography; methemoglobinemia; increased bronchial irritation; and increased intraocular pressure.

Complications.

Airplane glue has been responsible for a wide range of complications, relating to chemical toxicity, to the method of administration (e.g., in plastic bags, with resultant suffocation), and to the often dangerous setting in which the inhalation occurs (e.g., inner-city roof tops). Gasoline toxicity is acute as well as chronic. Death in the acute phase may result from cerebral or pulmonary edema or myocardial involvement. Chronic use may cause pulmonary hypertension, restrictive lung defects or reduced diffusion capacity, peripheral neuropathy, acute rhabdomyolysis, hematuria, tubular acidosis, and possibly cerebral and cerebellar atrophy. Other behavioral

disturbances such as inattentiveness, lack of coordination, and general disorientation have been linked to chronic solvent abuse.

Diagnosis.

The brief effect of the inhalants makes it unlikely to diagnose unless there is a complication or death from use. Complete blood counts, coagulation studies, and hepatic and renal function studies may identify the complications. In extreme intoxication, a user may manifest symptoms of restlessness, general muscle weakness, dysarthria, nystagmus, disruptive behavior, and occasionally hallucinations, placing inhalant use in the differential diagnosis for acute intoxication of an adolescent. Toluene is excreted rapidly in the urine as hippuric acid, with the residual detectable in the serum by gas chromatography.

Treatment.

Treatment is generally supportive and directed toward control of arrhythmia and stabilization of respirations and circulation. Withdrawal symptoms do not usually occur.

105.6 Hallucinogens

Several naturally occurring and synthetic substances have been used by adolescents for their hallucinogenic properties. Lysergic acid diethylamide (LSD) and methylenedioxymethamphetamine (MDMA) or Ecstasy are the most commonly reported hallucinogens in high school. Among high school seniors in 2001, 12.8% reported ever using a hallucinogen, with 10.9% reporting the use of LSD, and 11.7% reporting the use of MDMA. These reports reflect a decreasing trend in use from 1997, with the exception of MDMA, which increased. National household survey rates in 2000 for all hallucinogens report lifetime use for 12–17 yr olds at 5.8%, with use in the prior year at 3.9%. Illicit drugs sold on the street are not labeled and are frequently misrepresented. In one survey, 11% of the confiscated drugs submitted as LSD to the Los Angeles County Street Drug Identification Program contained no identifiable LSD. The reported experiences with these drugs still represent a significant level of experimentation with dangerous chemicals.

LYSERGIC ACID DIETHYLAMIDE

LSD (acid, big “D,” blotters) is one of the constituents found in rye fungus. Morning glory seeds contain lysergic acid derivatives, although the commercially packaged varieties have often been treated with toxic chemicals such as insecticides and fungicides. Although the specific mechanisms of action of LSD are still under study, it is proposed to alter neurotransmitters mediated by serotonin. LSD is a very potent hallucinogen with doses as low as 20?µg causing effects in some individuals. Its high potency allows effective doses to be applied to objects as small as postage stamps and paper blotters. It is rapidly absorbed from the gastrointestinal tract. The onset of action can be between 30 and 60?min, and it peaks between 2 and 4?hr. By 10–12?hr, an individual returns to the predrug state.

Clinical Manifestations.

The effects of LSD can be divided into three categories: somatic (physical effects), perceptual (altered changes in vision and hearing), and psychic effects (changes in sensorium). The common somatic symptoms are dizziness, dilated pupils, nausea, flushing, elevated temperature, and tachycardia. The sensation of synesthesia or “seeing” smells and “hearing” colors has been reported with LSD use. Delusional ideation, body distortion, and suspiciousness to the point of toxic psychosis are the more serious of the psychic symptoms.

Treatment.

An individual is considered to have a “bad trip” when the setting causes the user to

become terrified or panicked. These episodes should be treated by removing the individual from the aggravating situation or setting and attempting to re-establish contact with reality through calm verbal interaction. Any physical complications such as hyperthermia, seizure, or hypertension should be treated supportively. "Flashbacks" or LSD-induced states after the drug has worn off and tolerance to the effects of the drug are additional complications of its use.

METHYLENEDIOXYMETHAMPHETAMINE

MDMA ("X," Ecstasy), a phenylisopropylamine hallucinogen, is a synthetic compound similar to mescaline, commonly referred to as a "designer drug." Like other hallucinogens, this drug is proposed to interact with serotoninergic neurons in the CNS. It is the preferential drug at "raves," all night dance parties, and is also known as one of the "club drugs."

Clinical Manifestations.

Euphoria, a heightened sensual awareness, and increased psychic and emotional energy are acute effects. Compared with other hallucinogens, MDMA is less likely to produce emotional lability, depersonalization, and disturbances of thought. Adverse effects can be physical as well as psychic. Nausea, jaw clenching, teeth grinding, and blurred vision are somatic symptoms, whereas anxiety, panic attacks, and psychosis are the adverse psychic outcomes. A few deaths have been reported after ingestion of the drug. Hyperthermia in association with vigorous dancing at a "rave" has resulted in severe toxic reactions and death. There are *no specific treatment regimens* recommended for acute toxicity. There is evidence to suggest a link between prenatal MDMA exposure and cardiovascular and musculoskeletal birth defects.

PHENCYCLIDINE

PCP (sternyl, angel dust, "hog," "peace pill," "sheets") is an arylcyclohexalamine whose popularity is related, in part, to its ease

of synthesis in home laboratories. One of the by-products of home synthesis causes cramps, diarrhea, and hematemesis. The drug is thought to potentiate adrenergic effects by inhibiting neuronal reuptake of catecholamines. PCP is available as a tablet, liquid, or powder, which may be used alone or sprinkled on cigarettes ("joints"). The powders and tablets generally contain 2–6?mg of PCP, whereas joints average 1?mg for every 150?mg of tobacco leaves, or approximately 30–50?mg per joint.

Clinical Manifestations.

The clinical manifestations are dose-related. Euphoria, nystagmus, ataxia, and emotional lability occur within 2–3?min after smoking 1–5?mg and last for hours. Hallucination may involve bizarre distortions of body image that often precipitate panic reactions. With doses of 5–15?mg, a toxic psychosis may occur, with disorientation, hypersalivation, and abusive language lasting for more than 1?hr. Hypotension, generalized seizures, and cardiac arrhythmias commonly occur with plasma concentrations from 40–200?mg/dL. Death has been reported during psychotic delirium, from hypertension, hypotension, hypothermia, seizures, and trauma. The coma of PCP may be distinguished from that of the opiates by the absence of respiratory depression; the presence of muscle rigidity, hyperreflexia, and nystagmus; and lack of response to naloxone. PCP psychosis may be difficult to distinguish from schizophrenia. In the absence of history of use, analysis of urine must be depended on for diagnosis.

Treatment.

Management of the PCP-intoxicated patient includes placement in a darkened, quiet room on a floor pad, safe from injury. For recent oral ingestion, gastric absorption is poor and induction of emesis or gastric lavage is useful. Diazepam, in a dose of 5–10?mg orally or 2–5?mg intravenously, may be helpful if the patient is agitated and not comatose. Rapid excretion of the drug is promoted by acidification of the urine. Supportive therapy of the comatose patient is indicated with particular attention to hydration, which may be compromised by PCP-induced diuresis.

105.7 Cocaine

Crack cocaine, the highly addictive smokable form of cocaine, has increased availability and severity of cocaine use in the face of a decrease in use in the overall population. Lifetime or “ever use” in high school seniors dropped from a level of 17.3% in 1985 to 9.4% in 1990. Use in all grades peaked in 1999, and has declined or leveled off by 2001. Use of crack cocaine represents almost half the total cocaine use.

Cocaine, an alkaloid extracted from the leaves of the South American *Erythroxylon coca,* is supplied as the hydrochloride salt in crystalline form. It is rapidly absorbed from the nasal mucosa, detoxified by the liver, and excreted in the urine as benzoyl ecgonine. Its half-life is slightly more than 1?hr. The perceived effect of “snorting” cocaine may be influenced by some of the many diluents now being added to or actually substituted for the drug (heroin, amphetamines, PCP, or fillers such as mannitol or quinine). Smoking the cocaine alkaloid (“freebasing”) in pipes or cigarettes, mixed with tobacco, marijuana, parsley, or as a paste, has become a popular method of use. Accidental burns are potential complications of this practice. With crack cocaine, the smoker feels “high” in less than 10?sec. The technique for extracting crack cocaine does not involve ether and is a safer and simpler technique compared with making freebase cocaine. The risk of addiction with this method is higher and more rapidly progressive than from snorting cocaine. Tolerance develops and the user must increase the dose or change the route of administration, or both, to achieve the same effect.

Clinical Manifestations.

Cocaine produces euphoria, increased motor activity, decreased fatigability, and occasionally paranoid ideation. Its sympathomimetic properties are responsible for pupillary dilatation, tachycardia, hypertension, and hyperthermia. Binge patterns of use are common. Neurologic effects such as dizziness, paresthesias, and seizures can occur. Use in group settings has been associated with sexual promiscuity and increased risks of sexually transmitted infections. Lethal effects are possible, especially when cocaine is used in combination with other drugs, such as heroin, in an injectable form known as a “speedball.” Although addiction and tolerance develop in the chronic user, withdrawal symptoms on its discontinuation have not been reported, suggesting that physical dependency does not occur. Pregnant adolescents who use cocaine place their fetus at risk for premature delivery, complications of low birthweight, and possibly congenital malformations and developmental disorders.

Treatment.

Intensive supportive therapy is directed at the clinical manifestations of acute intoxication.

105.8 Amphetamines

Stimulants, particularly amphetamines, are among the most frequently reported illicit drugs other than marijuana used by high school seniors. Methamphetamine, commonly known as “ice,” accounted for more than 25% of stimulant use. Methamphetamine is particularly popular among adolescents and young adults because of its potency and ease of absorption. It can be used by snorting, smoking, ingesting by mouth, or absorption across mucous membranes, such as vaginal mucosa. Its use is especially common in the western and southwestern regions of the United States. Amphetamines have multiple CNS effects, among them the release of neurotramsmitters and an indirect catecholamine agonist effect. In high doses, they may also affect serotonergic receptors.

Clinical Manifestations.

The effects of amphetamines can be dose-related. High doses produce slowing of cardiac conduction in the face of ventricular irritability. Hypertensive and hyperpyrexic episodes can occur as can seizures. Binge effects result in the development of psychotic ideation with the potential for sudden violence. Cerebrovascular damage and psychosis can result from chronic use. There is a withdrawal syndrome associated with amphetamine use, with early, intermediate, and late phases. The early phase is characterized as a “crash” phase with depression, agitation, anergia, and desire for more of the drug. Loss of physical and mental energy, limited interest in the environment, and anhedonia mark the intermediate phase. In the final phase, drug craving returns, often triggered by particular situations or objects.

Treatment.

Agitation and delusional behaviors can be treated with haloperidol or droperidol. Phenothiazines are contraindicated and may cause a rapid drop in blood pressure or seizure activity. Other supportive treatment consists of a cooling blanket for hyperthermia and treatment of the hypertension and arrhythmias, which may respond to sedation with lorazepam (Ativan) or diazepam (Valium).

105.9 Opiates

Opiate abuse by adolescents decreased considerably during the 1980s, but the magnitude and variety of its medical sequelae warrant continued attention. Although it has been one of the least frequently reported drugs of use since 1991, heroin produces euphoria and analgesia. Heroin is hydrolyzed to morphine, which undergoes hepatic conjugation with glucuronic acid before excretion, usually within 24?hr of administration. It can be detected in urine by thin-layer chromatography up to 48?hr after administration. The route of administration influences the timing of the onset of action. When the drug is inhaled

---

(“snorting”), it requires almost 30?min before the desired effect is achieved. By the subcutaneous route (“skin-popping”), the effect is achieved within minutes; when injected intravenously (“mainlining”), it has an immediate effect. Tolerance develops to the euphoric effect and only rarely to the inhibitory effect on smooth muscle, which causes both constipation and miosis.

Clinical Manifestations.

The clinical manifestations are determined by the pharmacologic effects of heroin or its adulterants, combined with the conditions and the route of administration. The cerebral effects include euphoria, diminution in pain, and pinpoint pupils. An effect on the hypothalamus is suggested by the lowering of body temperature. Vasodilation is a major cardiovascular manifestation related to the method of administration of the drug. Respiratory depression is mediated centrally and is characterized by alveolar underventilation. Pulmonary edema is common in death from the overdose syndrome, but it may also be seen as an incidental roentgenologic finding in an otherwise asymptomatic adolescent heroin abuser. The most common dermatologic lesions are the “tracks,” the hypertrophic linear scars that follow the course of large veins. Smaller, discrete peripheral scars, resembling healed insect bites, may be easily overlooked. The adolescent who injects heroin subcutaneously may have fat necrosis, lipodystrophy, and atrophy over portions of the extremities. Attempts at concealment of these stigmata may include amateur tattoos in unusual sites. Abscesses secondary to unsterile techniques of drug administration are commonly found. There is a loss of libido; the mechanism is unknown. The female heroin user may resort to prostitution to support the habit, thus increasing the risk of sexually transmitted disease (including HIV), pregnancy, and other hazards. Constipation results from decreased smooth muscle propulsive contractions and increased anal sphincter tone. Hepatic enzyme activities are frequently elevated in heroin users, the majority of whom have serologic evidence suggesting viral infection with hepatitis B. The absence of sterile technique in injection may lead to cerebral microabscesses or endocarditis, usually caused by *Staphylococcus aureus*. Infection with HIV is another complication of needle use. Abnormal serologic reactions are also common, including false-positive Venereal Disease Research Laboratory and latex fixation tests.

WITHDRAWAL.

After a period of 8?hr or more without heroin, the addicted individual undergoes, during a period of 24–36?hr, a series of physiologic disturbances referred to collectively as “withdrawal” or the *abstinence syndrome*. The earliest sign is yawning, followed by lacrimation, mydriasis, insomnia, “goose flesh,” cramping of the voluntary musculature, hyperactive bowel sounds and diarrhea, tachycardia, and systolic hypertension. The occurrence of grand mal seizures is rare in adolescent addicts. The administration of methadone is the most common method of detoxification. This synthetic opiate is effective by the oral route and is pharmacologically similar to heroin, with the exception of its lack of euphoric effect. A short course of diazepam is also an effective and safe treatment for heroin detoxification.

OVERDOSE SYNDROME.

The overdose syndrome is an acute reaction after the administration of an opiate. It is the leading cause of death among drug users. The clinical signs include stupor or coma, seizures, miotic pupils (unless severe anoxia has occurred), respiratory depression, cyanosis, and pulmonary edema. The differential diagnosis includes CNS trauma, diabetic coma, hepatic (and other) encephalopathy, Reye syndrome, as well as overdose of alcohol, barbiturates, PCP, or methadone. Diagnosis of opiate toxicity is facilitated by intravenous administration of the opiate antagonist naloxone, 0.01?mg/kg (2?mg is a common initial dose for an adolescent), which causes dilation of pupils constricted by the opiate. Diagnosis is confirmed by the finding of morphine in the serum.

Treatment.

This consists of maintaining adequate oxygenation and continued administration of naloxone every 5?min, when necessary, to improve and maintain adequate ventilation. Naloxone may have to be continued for 24?hr if methadone, rather than shorter-acting heroin, has been taken.

105.10 Anabolic Steroids

The quest for enhanced athletic performance has led to the abuse of anabolic steroids by competitive athletes of both sexes. As with other substances, prevalence data vary across surveys. Reports of anabolic steroids having ever been used range from 0.7–3.7%, usually with male use predominating. However, two of three surveys show significant increases in females who had ever used anabolic steroids in the 1990s. Although the percentages are low, population estimates based on 1995 data suggest that about 375,000 males and 175,000 females of high school age have used anabolic steroids for performance enhancement. Use of anabolic steroids has been associated with a constellation of problem behaviors such as engaging in physical fights with injuries requiring medical attention, weapon carrying, binge drinking, and using other substances of abuse. The evidence for increased muscle mass and strength are controversial but are supported by objective data. The effects appear to be related to the myotrophic action at androgen receptors as well as competitive antagonism at catabolism-mediating corticosteroid receptors. Erythropoietic and psychologic effects may also contribute to their enhancement effects. The most common forms of anabolic steroids used are the oral 17-a-methyl derivatives of testosterone and the injectable esters of testosterone and 19-nortestosterone.

Clinical Manifestations.

Some of the adverse side effects of these drugs are reversible; others are not. The most immediate effects for all users is increasing acneform lesions. Other dermatologic manifestations include linear keloids, stria, oily hair, and hirsutism. These findings may be the first recognizable effects. Males can experience gynecomastia, breast pain, testicular atrophy, and azoospermia. Women experience more irreversible side effects such as breast atrophy, clitoral enlargement, and menstrual abnormalities. Serious psychologic effects also have been reported from the use of high doses of these agents (often 100 times the therapeutic doses), including uncontrollable rage, depression, mania, mood fluctuations, and alterations in libido. Users choosing the injectable route increase the risk of HIV if injection equipment is shared with others.

Abnormalities of the liver can be acute, such as hepatitis and hepatomegaly, or more long-term, such as the increased risk of hepatocellular carcinoma, particularly with the 17-a-alkylated forms. Fluid retention is a common side effect that prompts users to take diuretics. In addition to these effects, which occur in individuals of all ages, the early adolescent is at risk for growth retardation because of the possibility of accelerating epiphyseal closure.

Diagnosis and Treatment.

The clinical signs noted, coupled with a complete history, provide a diagnosis in most instances. Although urine testing is available and performed at the Olympic and collegiate competitive levels, few laboratories perform these tests and they are very expensive. Therefore, the secondary school approach primarily has been limited to education and prevention. Treatment is supportive.

Chapter 106 - The Breast

Renée R. Jenkins

Breast development is one of the first obvious signs of puberty, but it is often the focus of attention and a cause of anxiety in an adolescent, whether the issue is normal progression, some variation in progression, or a definable disorder. Normal breast development during puberty is described using a Sex Maturity Rating scale of 1–5, as the breast becomes more mature (see Chapter 14).

Normal Variants.

Minor breast asymmetry is common in adult females and sexually mature adolescent females. Other conditions that rarely occur but should be ruled out include *Poland syndrome* and unilateral breast aplasia, hypoplasia, or hypertrophy. Poland syndrome is marked by a hypoplastic breast nipple and areola with hypoplastic ipsilateral chest wall structures. Unilateral or bilateral juvenile (virginal) hypertrophy occurs with specific histopathologic changes but without any known cause. The enlargement may be mild and cause back pain and postural problems or severe enough to be associated with tissue and skin necrosis. Embarrassment and possible psychologic problems should be addressed in the management of this condition. Reconstructive surgical repair is indicated in severe breast asymmetry but is recommended after sex maturity rating 5 has been reached. Accessory breast tissue (polymastia) can also occur in males and females. This lesion can consist of a supernumerary nipple (polythelia) or breast tissue, or both, and usually occurs along both milk lines of the thorax and the abdomen. Accessory breast tissue beneath the umbilicus, though rare, can be associated with cardiovascular or genitourinary abnormalities.

Female Disorders (also see Chapter 543)

MASSES.

The most common adolescent breast disorder is a mass, the majority of which are benign cysts or fibroadenomas. *Cysts* vary in size over the course of a menstrual cycle, so a patient should be re-examined 2 wk after the initial examination. Persistence of the mass or its enlargement over three menstrual cycles is an indication for surgical consultation. Aspiration is usually attempted under local anesthesia, often resulting in curative drainage if it proves to be a cyst. If no fluid is

obtained, an excisional biopsy is indicated. When multiple small masses are palpable, associated with pain, a biopsy is rarely indicated. Most fibroadenomas are benign, mobile, well-defined rubbery feeling masses. Multiple fibroadenomas occur in 10–20% of patients. The *fibroadenoma* tends not to vary in size during the menstrual cycle, often distinguishing it from a cyst. *Cystosarcoma phylloides* is a rare variant of a fibroadenoma distinguished by having a more cellular stroma. It is typically larger than a fibroadenoma and can, rarely, be malignant.

In a review of 15 retrospective surgical studies of women younger than age 22 years, the most common lesion was the fibroadenoma (68.3%), followed by fibrocystic changes (18.5%). Malignancies occurred in 0.9% of cases with 5 primary breast cancer patients, and the others having Hodgkin lymphoma, lymphosarcoma, angiosarcomas, and other metastatic tumors. *Carcinoma* of the breast in the adolescent is rare. The efficacy and possible sequelae of mammography in managing adolescent breast masses are unknown. The dense breast tissue of the adolescent obstructs the visualization of a palpable mass; thus mammography is not advised for this age group. Ultrasonography is useful is distinguishing cystic from solid masses.

MASTALGIA.

Physiologic swelling and tenderness occur on a cyclic basis, most commonly during the premenstrual phase, and are secondary to hormonal stimulation and resulting proliferative changes. Nodularity, poorly localized tenderness, and a soreness radiating to the axilla and arm are usual accompanying findings. The preferable term for these changes is benign breast changes rather than the classic "fibrocystic disease." Non-cyclic mastalgia is less common in younger women compared with women in their 40s. Treatments recommended for this condition include firm support, heat, analgesics, hormonal therapy, diuretics, and evening primrose oil. Adult doses of evening primrose oil, two 500-mg capsules three times a day, has been associated with an overall response rate of 44%. A 3 mo trial is recommended with a follow-up treatment of 2 mo if the response is positive.

NIPPLE DISCHARGE.

Nipple discharge in adolescents is usually due to local stimulation; use of medications, including oral contraceptives; and pregnancy. Rarely, it results from a pituitary or breast neoplasm or infection. Examination of the discharge assists in diagnosis: Benign conditions are associated with a milky, sticky, thick discharge; infection is associated with a purulent discharge; and intraductal papilloma and cancer are associated with a serous, serosanguineous, or bloody discharge. Elevation of the serum prolactin level may occur in the *amenorrhea-galactorrhea syndromes,* associated with the use of certain

antihypertensive medications, oral contraceptives, or tranquilizers, or secondary to a pituitary adenoma. The latter is associated with central nervous system signs and is evaluated with a computed tomography scan or magnetic resonance imaging of the head. The possibility of a breast neoplasm is an indication for cytologic examination of the discharge and surgical consultation. Infection in the non–breast-feeding adolescent is rare and may be secondary to a human bite or the initial symptom of diabetes mellitus. Culture of the discharge, followed by appropriate antibiotic therapy (usually directed against *Staphylococcus aureus*) is indicated; surgical drainage is rarely necessary.

MALE DISORDERS.

Gynecomastia occurs in approximately one third of normal males during early to midpuberty and often causes concern that may not be openly voiced. The response should be factual information and reassurance of its usually transient nature. Rarely is it of such magnitude or persistence as to warrant surgery. Nonpubertal gynecomastia with hypogonadism is associated with Klinefelter syndrome and places a patient at a higher risk for breast cancer (see Chapter 577). Other conditions associated with nonpubertal gynecomastia are secondary to endocrine disorders, neoplasms, chronic disease, trauma, and medications as well as drugs of abuse (Box 106–1).

Chapter 107 - Menstrual Problems

Renée R. Jenkins

(See also Chapter 542 .)

Some variety of menstrual dysfunction occurs in about 50% of adolescent females. Most of the problems are minor; however, severe dysmenorrhea or prolonged menstrual bleeding can be debilitating to a teenager. Adolescents with mild dysfunction that does not require medical intervention should have their condition explained to them and should be reassured about their reproductive normalcy.

NORMAL MENSTRUATION

The age of normal menarche varies according to the characteristics of the population. In a large office-based study in the United States, 35% of white girls and 62% of African-American girls had initiated menses between ages 12 and 13 yr. The age of menarche in Tanner's English series ranges from ages 9–16 yr, with a mean age of 13.46 yr. The age of menarche is closely related to other parameters of pubertal maturation and correlated closely with bone age. The onset and continuation of normal menstrual cycling depends on the functional and anatomic integrity of (1) the hypothalamus together with higher centers, including possibly the pineal gland; (2) the anterior pituitary; (3) the ovary; and (4) the uterus. The percentage of body fat is also a factor in the onset of menarche, with a minimal fatness of 17% of body weight being necessary for the onset of menstrual cycles and a minimum of 22% fatness necessary to maintain regular ovulatory cycles. Menarche usually occurs about 2.3 yr after the initiation of puberty, with a range of 1–3 yr, and becomes regular after 2–2.5 yr. The length of the menstrual cycle from the first day of menses of one cycle to the first day of the next cycle can range from 21–45 days, although the average is about 28 days. Anovulatory cycles are generally longer. The average blood flow usually results in about 40?mL of blood loss with a range of 25–70?mL. The later the age of menarche, the longer until the establishment of ovulatory cycles.

Menstrual cycle irregularities are described according to variation in frequency of menses, amount, and both frequency and amount (Box 107–1). A complete history for evaluating a patient with menstrual dysfunction should include questions specifically related to puberty and menstrual patterns, a family history of gynecologic problems, and a past medical history noting hospitalizations, chronic illness,

medication or substance use, and infections. The related association of weight change, nutrition, exercise, and sports participation can be critically important in considering a differential diagnosis. Regardless of the age of the adolescent, an appropriate history of any type of sexual activity should be elicited, and the pediatrician should be cognizant of the need to rule out sexual abuse as an issue in young adolescents when other findings suggest sexual activity.

In addition to the basic growth parameters of weight, height, blood pressure, heart rate, and body mass index, signs of virilization should be assessed, such as hirsutism and clitoromegaly. A careful external and internal pelvic examination is a key to ruling out anatomic defects and accumulating additional specimens for the evaluation. In the young adolescent, this examination should be performed by someone with expertise in this age group and with the proper-sized equipment.

MENSTRUAL IRREGULARITIES

Etiology.

The distinction among menstrual irregularities is somewhat artificial given that the causes of the entities are often similar, e.g., many of the problems of pubertal delay, such as Turner mosaic syndrome, may present as primary amenorrhea or secondary amenorrhea. Thyroid disorders also can be the source of secondary amenorrhea or abnormal vaginal bleeding. The common cause of all of these disorders is a disturbance of the hypothalamic-pituitary-ovarian axis. The amenorrheic disorders are categorized on the basis of follicle-stimulating hormone (FSH) levels into hypergonadotropic hypogonadism (ovarian failure) and hypogonadotropic hypogonadism (hypothalamic or pituitary dysfunction). FSH-luteinizing hormone (LH) patterns in perimenarcheal girls with anovulatory bleeding also suggests the prevalence of a maturational defect for normal negative feedback cyclicity. The rising levels of estrogen do not

Box 107-1. Terms for Menstrual Cycle Irregularities

Variations in frequency

Polymenorrhea: frequent regular or irregular bleeding at <21-day intervals

Oligomenorrhea: infrequent irregular bleeding at >45-day intervals

Primary amenorrhea: no menstrual flow by age 16 yr

Secondary amenorrhea: absence of vaginal bleeding for > 3 mo

Irregular menses: bleeding at varying intervals, =21-day intervals but <45-day intervals

Variations in amount

Hypomenorrhea: decreased menstrual flow at regular intervals

Hypermenorrhea: profuse menstrual flow of normal duration at regular intervals

Variations in amount and duration

Metrorrhagia: intermenstrual irregular bleeding between regular periods

Menorrhagia: excessive amount and increased duration of uterine bleeding occurring regularly

Menometrorrhagia: frequent irregular, excessive, and prolonged episodes of uterine bleeding

Dysfunctional uterine bleeding: prolonged excessive menstrual bleeding associated with irregular

excessive, and prolonged episodes of uterine bleeding

Dysfunctional uterine bleeding: prolonged excessive menstrual bleeding associated with irregular periods: usually due to immaturity of reproductive axis in adolescence if within first 2 yr of menarche

From Blythe MI: Common menstrual problems of adolescence. Adolesc Med 1997; 8:87.

cause a fall in FSH and the subsequent suppression of estrogen secretion, and consequently the endometrium becomes thickened, promoting irregular and heavier blood flow with shedding.

Psychogenic factors have been implicated in amenorrhea. It is often difficult to separate psychologic from nutritional factors because weight loss is a common confounding variable in many of these situations, for example, depression, anorexia nervosa, or stress.

Clinical Manifestations.

Amenorrhea, or absence of menses, may be primary or secondary. The diagnosis of primary amenorrhea assumes that the patient has passed the age at which menarche normally occurs, from 10–16 yr. Accordingly, the determination of primary amenorrhea should first be based on an assessment of the patient's stage of pubertal development; 10% of girls have menarche at Sex Maturity Rating (SMR) 2, 20% reach menarche at SMR 3, 60% reach it at SMR 4, and 10% reach menarche at SMR 5. If the patient has not entered puberty by the expected time or if pubertal development is completed without the onset of menses, she should be thoroughly evaluated, even if her chronological age is within the normal range. Similarly, the close concordance of the age of menarche between daughters and mothers and among siblings should suggest this diagnosis when the patient is more than 1 yr older than were the mother or sisters when their menarche occurred. The distinguishing characteristic of the clinical presentation of amenorrhea is the presence or absence of virilization. Clinical features such as clitoromegaly, hirsutism, or excessive acne are associated with adrenal or ovarian disease. Other clinical presentations such as slender or obese body habitus or short stature also are characteristic of syndromes associated with amenorrhea.

The first consideration in the adolescent who presents with secondary amenorrhea is pregnancy. This possibility also exists, albeit rarely, as a cause of primary amenorrhea, if fertilization of the first released ovum occurred before menses. A history of sexual intercourse, nausea, and breast tenderness and physical findings of increased pigmentation of nipples and linea alba, cyanosis and softening of the cervix, and an enlarged uterus form the classic picture.

In the clinical presentation of abnormal vaginal bleeding, mild to moderate bleeding may present without any specific clinical findings; however, severe bleeding is accompanied by the abnormal vital signs associated with hypovolemia. Very severe bleeding may progress to syncope and death, making this one of the few gynecologic emergencies of adolescence.

107.1 Amenorrhea

Differential Diagnosis.

In *primary amenorrhea,* chromosomal or congenital abnormalities, such as gonadal dysgenesis, the triple X syndrome, isochromosomal abnormalities, testicular feminization syndrome, and, rarely, true hermaphroditism, should be considered in addition to the conditions that cause secondary amenorrhea. Elevated levels of FSH and LH suggest primary gonadal failure, and chromosome analysis elucidates its cause. When primary amenorrhea occurs with advanced pubertal development, a structural anomaly of the müllerian duct system should be suspected. *Imperforate hymen* is most common and is associated with recurrent (monthly) abdominal pain and, after some time has passed, a midline lower abdominal mass, the blood-filled vagina, or *hematocolpos.* Diagnosis is made by inspection of the introitus, revealing a bulging hymen with bluish discoloration. If the obstruction is at the level of the cervix, the blood-filled uterus *(hematometrium)* is apparent on bimanual examination or ultrasonography. Agenesis of the cervix or uterus is rare but occurs in association with sacral agenesis.

Primary or *secondary* amenorrhea may also be caused by chronic illness, particularly that associated with malnutrition or tissue hypoxia, such as diabetes mellitus, inflammatory bowel disease, cystic fibrosis, or cyanotic congenital heart disease. In most cases, the illness has been diagnosed previously but, occasionally, the amenorrhea is its first manifestation. Polycystic ovarian syndrome is one of the most common endocrine disorders affecting premenopausal women and presents with menstrual abnormalities from amenorrhea to dysfunctional uterine bleeding. A central nervous system (CNS) tumor, most commonly a craniopharyngioma, may present with amenorrhea. Prolactinomas, although rare, are the most common pituitary tumor in adolescence. Abnormalities of the thyroid gland, typically hyperthyroidism, may first be suspected by delayed sexual maturation or amenorrhea, even in the absence of other signs and symptoms. Hypothyroidism may cause precocious puberty but may also be associated with delayed puberty or abnormal uterine bleeding. Anorexia nervosa, which may present with either primary or secondary amenorrhea, is occasionally confused with hyperthyroidism because of weight loss, hyperactivity, and personality changes seen in both entities. Ingestion of drugs, both legal and illegal, may cause amenorrhea and, in the case of phenothiazines, even a false-positive urine pregnancy test. Some drugs, including phenothiazines and certain antihypertensive agents, may cause galactorrhea, further mimicking pregnancy. A thorough drug history is, therefore, necessary.

Laboratory Findings.

The approach to the clinical evaluation of delayed menarche (Fig. 107–1) suggests a stepwise progression initiated by the history and physical examination. The pregnancy test, preferably a qualitative serum ß-subunit human chorionic gonadotropin (hCG), is the key laboratory test to perform in the evaluation of secondary amenorrhea (Fig. 107–2) regardless of the history or sexual activity given by the patient or signs of virilization. The next step for laboratory determinations follows the scheme and is performed according to the individual's response to an initial progesterone challenge or after the findings of the vaginal smear for estrogen. The direct correlation of bone age to menstrual age enhances the value of a radiograph before proceeding with an extensive work-up. The measurement of FSH is critical in determining whether chromosomal abnormalities (with FSH elevation > 25?mIU/mL) or other endocrinopathies or CNS tumors (with normal or low FSH < 5?mIU/mL) are present.

Prolonged amenorrhea (>6 mo) and persistent oligomenorrhea without an explanation should prompt the measurement of thyroid-stimulating hormone, FSH, LH, and prolactin levels, even in the face of a normal progesterone challenge. Elevated LH and normal FSH levels require the measurement of androgen excess even in the absence of obvious virilization. An LH:FSH ratio greater than 3 and an elevated free testosterone level is common in adolescents with **polycystic ovary syndrome** (PCOS). Hyperinsulinemia is a characteristic feature of PCOS, and there is an increased risk of diabetes mellitus. The criterion for the diagnosis of PCOS is menstrual irregularity in the face of androgen excess with either hirsutism, acne, or increased serum androgens (also see Chapter 544). An elevated prolactin level or other clinical features suggesting a CNS tumor should be followed up with cranial computed tomography scan or, preferably, magnetic resonance imaging.

Endometrial status can be assessed as part of the evaluation when other endocrinologic parameters are normal by a progesterone challenge in which 5 or 10?mg of oral medroxyprogesterone acetate is given for 5 to 10 days. Withdrawal bleeding should occur 2–7 days thereafter when normal endometrium is present. If bleeding does not occur, one must consider insufficient estrogenic priming of the endometrium, an abnormal uterus, or an outflow tract obstruction.

Treatment.

Determination of the cause of amenorrhea may permit the initiation of corrective intervention. When the disorder is not amenable to remediation, consideration should be given to establishing regular pseudomenses to allow the adolescent to

Figure 107.1-1 Delayed menarche. (From Emans SJH, Laufer MR, Goldstein DP [editors]: *Pediatric and Adolescent Gynecology*, 4th ed. Philadelphia, Lippincott-Raven, 1998.)

feel like her peers. If the result of a vaginal smear is positive for estrogen effect, regular cycling can be accomplished using medroxyprogesterone in a dose of 10?mg orally for 10–12 days at least every other month. Combination oral contraceptives

can also be used for this purpose in patients with PCOS. In a patient with gonadal dysgenesis, conjugated estrogens must be given first (Premarin in an oral dose of 0.3?mg and increased to 1.25?mg) for feminization to progress. This is followed by medroxyprogesterone, 10?mg orally on days 10–21 of the cycle.

107.2 Abnormal Uterine Bleeding

Differential Diagnosis.

Most abnormal vaginal bleeding in adolescents results from anovulatory cycles, normally occurring in the 1st yr of menarche. This is called *dysfunctional uterine bleeding;*

Figure 107.2-2 Evaluation of secondary amenorrhea. (From Emans SJH, Laufer MR, Goldstein DP [editors]: *Pediatric and Adolescent Gynecology*, 4th ed. Philadelphia, Lippincott-Raven, 1998.)

this term is used when no demonstrable organic lesion is identified to account for the abnormal bleeding. Organic lesions are found in about 9% of 10–20 yr old young women; the most common include ectopic pregnancy, threatened abortion, endometritis, and hormonal contraceptives. Box 107–2 lists the full differential diagnosis, which is extensive; however, studies of severe cases that require hospitalization report coagulation disorders (idiopathic thrombocytopenic purpura, von Willebrand disease, leukemia), Glanzmann disease, hypothyroidism, thalassemia major, Fanconi syndrome, and rheumatoid arthritis as the most frequent diagnoses.

Laboratory Findings.

The hemoglobin and hematocrit from a complete blood count are the most important elements in the initial evaluation. They establish the severity of the bleeding, with levels less than a hemoglobin of 9?g/dL or a hematocrit of 27% considered severe, 9–11?g/dL and 27–33% considered moderate, and greater than 11?g/dL and greater than 33% considered mild. Hospitalization is generally recommended for adolescents with a hemoglobin less than 7?gm/dL or a hemoglobin less than 10?gm/dL with significant postural blood pressure changes or excessive heavy bleeding. For sexually active teenagers, tests for gonorrhea, chlamydia, and pregnancy are also performed. The secondary evaluation should include liver and thyroid function studies, prothrombin time, partial thromboplastin time, and bleeding time. If these studies are not performed at the first visit, they must be performed before any estrogen therapy is initiated that might interfere with interpreting the results.

Treatment.

In mild cases, iron supplementation is recommended, and the patient should keep a menstrual calendar to follow the subsequent flow patterns. With moderate disturbances, cycling with oral contraceptives, barring any contraindications, should be considered along with monitoring the iron status. Severe bleeding, not requiring hospitalization, can usually be stopped with hormonal therapy, either medroxyprogesterone acetate (Provera) 10?mg/24?hr for 10–14 days or a combination oral contraceptive (OC) using two to four pills per day until the bleeding stops, then one pill per day for the remainder of the cycle. Once a patient is hospitalized, Premarin 20–40?mg every 4?hr up to 24?hr given intravenously is required. At the same time, the combination oral contraceptive regimen or Depo-provera (medroxyprogesterone acetate [DMPA]), 150?mg IM every 12 wk, required for maintenance can be initiated. These estrogen doses are high, but no complications have been reported from short-term use.

In the rare case of a patient whose bleeding cannot be controlled by one of these methods, an endometrial curettage may be indicated. Although this procedure is frequently undertaken in adult women with menometrorrhagia, the rarity of endometrial carcinoma and the usual efficacy of hormonal therapy in adolescence make this procedure unnecessarily invasive in this age group.

107.3 Dysmenorrhea

Painful menstrual cramps are experienced by nearly two thirds of postmenarcheal teenagers in the United States. More than 10% of this group suffer sufficiently to miss school, making dysmenorrhea the leading cause of short-term school absenteeism in female adolescents. Dysmenorrhea may be primary or secondary. *Primary dysmenorrhea* is characterized by the absence of any specific pelvic pathologic condition and is the more commonly occurring form. Prostaglandins F_2 and E_2 , produced by the endometrium, stimulate the myometrium to contract, producing pain. *Secondary dysmenorrhea* results from an underlying **structural abnormality** of the cervix or uterus, a **foreign body** such as an intrauterine device, **endometriosis**, or **endometritis.** Endometriosis, a condition in which implants of endometrial tissue are found at ectopic locations within the peritoneal cavity, is being diagnosed with increasing frequency among adolescents through the use of ultrasonography and laparoscopy. Characteristically, there is severe pain at the time of menses; its specific location depends on the site of the implants.

A pelvic examination must be performed to exclude the causes of secondary dysmenorrhea, and if none is found, a diagnosis of primary dysmenorrhea should be considered. Adolescents suffering from dysmenorrhea have high levels of prostaglandins F_2 and E_2 and experience symptomatic relief when prostaglandin synthetase inhibitors are administered. If given before a menstrual period (or shortly after it begins), administration of a rapidly absorbed prostaglandin synthetase inhibitor, such as naproxen sodium, is effective in destroying the prostaglandins before they produce pain (e.g., two tablets of 275?mg each taken with the onset of menses and one tablet taken every 6–8?hr after that for the 1st 24?hr). Medication is rarely needed beyond the 1st day. For the teenager with dysmenorrhea who requires contraception, oral contraceptive therapy may be indicated. It is not certain whether the beneficial effect of such use derives from the ability of oral contraceptives

to inhibit ovulation and thus eliminate progesterone production from the corpus luteum or from their ability to limit endometrial proliferation and therefore the production of prostaglandins.

In adolescent patients with endometriosis, danazol, an antigonadotropin, is rarely prescribed because of the unacceptable side effects of weight gain, edema, irregular menses, acne, oily skin, hirsutism, and a deep voice change. The use of gonadotropin-releasing hormone (GnRH) agonists such as nafarelin and leuprolide are more commonly used with the goal of the creation of an acyclic, low-estrogen environment. This prevents bleeding at the site of the implants and further seeding of the pelvis during retrograde menstruation. To reduce the risk of decreased bone density, a long-term side effect of gonadotropin-releasing hormone analog therapy, prescriptions for courses of therapy lasting longer than 6 consecutive mo are not recommended.

107.4 Premenstrual Syndrome

Premenstrual syndrome, or the late luteal phase syndrome, is a complex of physical signs and behavioral symptoms occurring during the second half of the menstrual cycle, which may resolve with the onset of menses. Clinical manifestations may include breast fullness and tenderness; bloating; fatigue; headache; increased appetite, especially for sweets and salty foods; irritability and mood swings; and depression, inability to concentrate, tearfulness, and violent tendencies. About one third of women in the reproductive age group may have premenstrual syndrome, but the absence of objective findings makes this difficult to corroborate. It is not common among adolescents, and it does not relate to the presence of dysmenorrhea, which is much more common in this age group. The popular use of vitamin B_6 and progesterone supplementation is not based on evidence of their effectiveness, nor is there a theoretical basis for their use. Use of a gonadotropin-releasing hormone agonist on a short-term basis is supported by carefully controlled studies, but long-term effects, such as osteoporosis and potential complications, have not yet been evaluated, making its use in adolescents contraindicated.

Chapter 108 - Contraception

Renée R. Jenkins

Adolescents bear a disproportionate risk for the adverse consequences of sexual activity, sexually transmitted diseases, and early unintended pregnancy. They should be encouraged to postpone sexual activity; however, contraceptive counseling and services should be offered to adolescents who are sexually active.

Epidemiology.

The National Survey of Family Growth (1995) reported a decline in sexual activity from 1988–1995, with intercourse in young women aged 15–19 yr dropping from 55–50% and percentages in young men dropping from 60–55%. The Centers for Disease Control and Prevention's Youth Risk Behavior Survey supports this observation in high school students with “ever had intercourse” rates falling from 54.1% in 1991 to 49.9% in 1999. The survey specifically notes that 64.9% of high school seniors report having ever had intercourse, with 50.6% currently active sexually, which was defined as having had intercourse during the 3 mo preceding the survey. In 9th grade, 38.6% reported ever having had sex, with 26.6% being sexually active. Many factors are associated with early sexual activity, including but not limited to lower expectations for education, poor perception of life options, low school grades, and involvement in other high-risk behaviors.

There is some variability in the reporting of the percentage of teenagers who use contraception depending on the study and the way in which the question was worded. Overall contraceptive use among adolescents aged 15–19 yr, according to the National Survey of Family Growth, increased significantly from 1982–1988 (24.2–32.1%); however, more recent data demonstrate a decline between 1988 and 1995 (29.8%). Contraceptive use at first intercourse, and condom use in general, have increased during this same period. The type of method selected also varies by ethnicity, with nonwhite teens more likely to select pills, and black teens using pills as the first choice, but being two times more likely than whites to use an injectable method (Table 108–1). In a 5-country study of developed nations, United States teens used medical methods at last intercourse less frequently compared to other teens; 52% in U.S. teens, 56% in Swedish 18–19 yr olds, 67% of French 15–19 yr olds, 72% of British 16–19 yr olds, and 73% of Canadian 15–19 yr olds. Sexually active adolescent women in the United States delay going to a clinic or a doctor for a medical contraceptive for an average of 6 mo after initiating intercourse. A higher likelihood of contraceptive use is associated with older age at sexual initiation, aspirations for higher academic achievement, acceptance of one's own sexuality, and a positive attitude toward contraception.

Contraceptive Counseling.

The health screening interview during the adolescent preventive visit offers the opportunity both to support the adolescent who is abstinent to continue to be so and to identify the sexually active adolescent who has unsafe sexual

practices (see Chapter 100). Adolescents with chronic diseases are particularly vulnerable to having these issues omitted from the health maintenance visit. There may be particular cautions related to concurrent medication to be noted for these chronically ill teenagers; however, sexuality and contraceptive issues need to be addressed. The goals of a counseling intervention with the adolescent are to understand the adolescent's perceptions and misperceptions about contraceptives, help him or her put the risk of unprotected intercourse in a personal perspective, and educate the adolescent regarding the real risk and contraindications for the various methods available. The likelihood that an adolescent will use a contraceptive method depends on such factors as the developmental level of the adolescent, the reproductive history, the involvement in other high-risk behaviors, and the degree of readiness for using contraception. Readiness to use contraception progresses in stages, from (1) precomtemplative, not thinking about using contraception, (2) contemplative—giving it some thought, but having no immediate plans, (3) preparative, wanting to try a method in the near future, to (4) active—using contraception. The adolescent should also be made aware of the “perfect” use failure rates vs the “typical” failure rates based on patient compliance (Table 108–2). Once an adolescent chooses a method, recognition of the common side effects, with clear plans on management, communication with the provider about the realistic expectation for failure, and a contingency plan for that possibility between the adolescent and the provider give closure to the counseling session and provide strategies for close follow-up. The use of withdrawal as a method is probably underestimated in adolescents and its low efficacy rate should be specifically addressed with young adolescents. The pelvic examination as a requirement to obtain medical contraception creates a barrier for some teenagers; consequently, clinicians have commonly delayed the examination for 3–6 mo for adolescents who might otherwise postpone the acceptance of a contraceptive device. Confidentiality and consent issues related to contraceptive management are discussed in Chapter 100 .

108.1 Barrier Methods

Condoms.

This method prevents sperm from being deposited in the vagina. There are no major side effects associated with the

use of a condom. The AIDS scare appears to have increased the use of condoms among adolescents, with 46.2% of high school students reporting using a condom at last sexual intercourse in 1991 increasing to 58% in 1999. The main advantages of condoms are their low price, availability without prescription, little need for advance planning, and, most important for this age group, their effectiveness in preventing transmission of sexually transmitted diseases, including human immunodeficiency virus (HIV). Condoms are recommended as protection against sexually transmitted diseases (STDs), to be used along with all non-barrier medical methods for adolescents. A female condom is now available over the counter in single size disposable units. It is a second choice over the male latex condom because of the complexity of properly using the device, its low typical efficacy rate, and the lack of evidence demonstrating its effectiveness against STDs. Most adolescents would require intensive education and hands-on practice to use it effectively.

Diaphragm and Cervical Cap.

These methods have few side effects but are much less likely to be used by teenagers. Adolescents tend to object to the messiness of the jelly or to the fact that the insertion of a diaphragm may interrupt the spontaneity of sex, or they may express discomfort about touching their genitals.

108.2 Spermicides

A variety of agents containing the spermicide nonoxynol-9 are available as foams, jellies, creams, films, or effervescent vaginal suppositories. They must be placed in the vaginal cavity shortly before intercourse and reinserted before each subsequent ejaculation in order to be effective. Rare side effects consist of contact vaginitis. There has been some concern regarding the vaginal and cervical mucosal damage observed with nonoxynol-9, and the overall impact on HIV transmission is unknown. Effectiveness is in the range of the barrier methods (approximately 85%), and the finding that nonoxynol-9 is gonococcocidal and spirocheticidal enhances the attractiveness of these agents for adolescents because of their disproportionately high risk for STDs. Spermicides alone probably do not provide protection against STDs, but they should be used in combination with condoms.

108.3 Combination Methods

The conjoint use of the condom by the male and spermicidal foam by the female adolescent is extremely effective; the failure rate is 2% (perfect use), without any of the potential side effects and complications associated with the use of other forms of contraception having comparable efficacy. This combination also prevents STDs, including HIV.

108.4 Hormonal Methods

Hormonal methods currently employ either an estrogenic substance in combination with a progestin or a progestin alone. The action of the estrogen-progestin combination is to prevent the surge of luteinizing hormone and, as a result, to inhibit ovulation. Progestin may prevent ovulation, but it is not reliable. Progestin does, however, affect fallopian tube transport and the composition of cervical mucus in such a way as to make fertilization or implantation less likely.

Combination Oral Contraceptives.

Oral contraceptives (OCs) are commonly referred to as “the pill” and currently contain either 50, 35, 30, or 20?µg of estrogenic substance, typically either mestranol or ethinyl estradiol, and a progestin. The pill is one of the most reliable contraceptive methods available, with a perfect-use pregnancy rate in the range of 0.1%/yr. Typical-use failure

rates in 15–19 yr old women have ranged up to 18.1%. Thrombophlebitis, hepatic adenomas, myocardial infarction, and carbohydrate intolerance are some of the more serious potential complications of exogenous estrogen use. These disorders are, however, exceedingly rare in adolescents. Even though teenage smokers who use OCs have a relative risk of more than 2.0 for myocardial infarction, the likelihood of its occurrence is much smaller, and thus insignificant, than the risk of dying from pregnancy-related complications. Some long-range beneficial effects of estrogen use include decreased risks of benign breast disease, ovarian disease, and anemia.

The short-term adverse effects of OCs, such as nausea and weight gain, often interfere with compliance in adolescent patients. These effects are usually transient and may be overshadowed by the beneficial effects of a shortened menses and the relief of dysmenorrhea. The inhibition of ovulation or the suppressant effect of estrogens on prostaglandin production by the endometrium make OCs effective in preventing dysmenorrhea (see Chapter 107). An initial concern for younger adolescents regarding the potentially untoward effect of estrogens on epiphyseal growth has diminished. This does not occur, either because the amount of estrogen in OCs is small or because they are taken at a time when most growth has been completed. Amenorrhea occurring after cessation of OC use is seen with greater frequency in adolescents than in adults. It may persist for up to 18 mo after the discontinuation of the pill. The increased risk may not be due to age alone but may reflect oligomenorrhea or low body weight (<47?kg) before the initiation of use of the

pill. Acne may be worsened by some and improved by other OC preparations. The newer pills with nonandrogenic progestins are particularly effective in reducing acne and hirsutism as side effects. An additional beneficial cardiovascular effect occurs for adolescents taking estrogen-containing OCs; these young women have higher levels of cardioprotective high-density lipoproteins than controls.

Contraindications to the use of estrogen-containing OCs include hepatocellular disease, migraine headaches, breast disease, any condition in which hypercoagulability may be a problem (e.g., replaced cardiac valve, thrombophlebitis, sickle cell anemia) because of the increased levels of factor VIII and decreased production of antithrombin III, and known or suspected pregnancy. The risks of pregnancy must be balanced against the benefits of reliable contraception in patients with chronic diseases such as diabetes, epilepsy, and sickle cell disease. The initial history taken before prescribing OCs should specifically address these risks. Table 108–3 also presents the potential alterations of various laboratory tests that can occur in patients taking OCs.

Other Combination Methods.

A *monthly injectable* (estradiol cypionate, 5?µg, and medroxyprogesterone, 25?mg, MPA/E_2 C, Lunelle) provides the efficacy of the oral contraceptive and the convenience of a monthly injectable. It is administered by a health provider during the first 5 days of the menstrual cycle. The follow-up doses are given every 28 ± 5 days (23–33 days). The mechanism of action and side effect profile are similar to oral contraceptives.

The *transdermal patch* (Evra) contains ethinyl estradiol and norergestromin and is applied to the lower abdomen, buttocks, or upper body. It is worn continuously for 1 wk and changed weekly for a total of 3 wk, then removed to allow menstrual bleeding. It should not be applied to the breast. It appears to be less effective in women who weigh 198 pounds or more, and the common side effects are accidental detachment and skin irritation. Early studies in adults suggest improved compliance with the transdermal patch compared with oral contraceptives.

The *vaginal contraceptive ring* (NuvaRing) is a flexible, transparent, colorless vaginal ring that measures about 2.1 inches in diameter and is inserted into the vagina by the patient. It contains ethinyl estradiol and etonogestrel and remains in place for

3 wk, during which time these hormones are absorbed. If the ring is accidentally expelled, it should be reinserted; however, if it is out of place for more than 3?hr, a back-up method of contraception should be used.

All of these methods have similar contraindications to oral contraceptives (i.e., smoking, cardiovascular disease, and others).

All-Progestin Contraceptives.

Progestin-only contraceptives are available for the adolescent in whom the use of estrogen is potentially deleterious, for example, those with liver disease, replaced cardiac valves, or hypercoagulable states. These agents (“mini-pills”) are less reliable in inhibiting ovulation and are associated with a 0.5%/yr pregnancy rate (perfect use). Acceptance by adolescents is limited by the necessity of taking

Figure 108.4-1 (Figure Not Available) Emergency contraception using emergency contraceptive pills (ECPs). COC = combination oral contraceptive. (From Hatcher RA, Nelson AL, Zieman M, et al: *A Pocket Guide to Managing Contraception.* Tiger, GA, Bridging the Gap Foundation, 2001.)

the pill daily, the higher incidence of amenorrhea, and increased bleeding.

An *injectable progestin,* medroxyprogesterone (Depo-Provera, DMPA), is highly effective in birth control, with failure rates typically at 0.3–0.4%. This substance needs to be administered only once every 3 mo and is completely reversible in its anovulatory action; furthermore, the cessation of menses is conterminous with its use. The most common side effect of DMPA is menstrual disturbance, either amenorrhea or abnormal vaginal bleeding. Weight gain and lowered bone density have been observed in women taking DMPA; however, the data confirming the agent as the sole cause of these changes are still under study. Issues relative to bone density are of particular concern during adolescence, the developmental period in which the accumulation of bone density is at its greatest. Studies thus far indicate that the effect is reversible on discontinuation of the drug. Until further research is available, one should probably avoid DMPA use in teens at risk for osteoporosis, such as those who have chronic renal disease, who are wheelchair-bound, or who have eating disorders or chronic amenorrhea. In contrast, DMPA is particularly attractive for adolescents who have difficulty with compliance, mentally retarded teenagers, and teenagers with chronic illnesses who have a relative contraindication to estrogen use. Continuation rates are somewhat disappointing and range from 27–45% at 12 months, comparable to adult rates.

A *long-acting progestational agent*, levonorgestrel (Norplant), is contained in six small Silastic tubes that can be implanted subcutaneously. The contraceptive potency remains for 5 yr. This method is the most effective of all reversible birth control methods available, with a typical 1st-yr failure rate for all women at 0.09% and 5-yr failure rates at 0.9–1.1%. Failure rates specifically calculated for adolescent women are not available. Implants have been used primarily in postpartum adolescents with good tolerance and acceptability. When compared with OC use in this population, implant users have better continuation rates and fewer pregnancies over a 1–2 yr period. Requests for early removal of this device have led to its diminished use in adolescent women. Norplant II, with two Silastic rods to be implanted for 3 yr has been approved by the FDA with a similar efficacy and safety profile as Norplant. Another 3-year implant with a single rod containing 3-ketodesogestrol has undergone clinical trials in the United States and Europe. Data on the use of these products in adolescents are not available.

108.5 Emergency Contraception

Unprotected intercourse at midcycle carries a pregnancy risk of 20–30%. At any other time during the cycle, the risk drops to 2–4%. The risk may be reduced or eliminated by intervention within 72?hr after unprotected intercourse. Outside the United States, several agents are used for emergency contraception (EC): oral high-dose estrogens, high-dose combination estrogen-progestins, high-dose progestins, danazol, mifepristone, and the postcoital insertion of a copper intrauterine device (IUD). Strategies are under way to promote more widespread use of EC to reduce unintended pregnancies. One controlled trial with young women documented 2 times as likely use of EC if given in advance as compared to a group who received counseling alone. A protocol for approaching EC is outlined in Figure 108–1 (Figure Not Available) . The Yuzpe method is commonly used in the United States, consisting of combination pills totaling 200?µg of ethinyl estradiol and 2.0?mg of norgestrel or 1.0?mg levonorgestrel. Pills that can be utilized for this method appear in Figure 108–1 (Figure Not Available) . The high-dose combination OCs disrupt the luteal phase hormone pattern, creating an unstable and unsuitable uterine lining for implantation. If used midcycle, when ovulation is about to occur, the high-dose estrogen and progestin blunt the luteinizing hormone surge and impair ovulation. This method is effective in reducing the risk of pregnancy by 75%. An emergency contraceptive kit prepackaged for this method (Preven) is FDA approved. The most common side effect is nausea (50%) and vomiting (20%), prompting some clinicians to prescribe or recommend antiemetics along with the OCs. In most health care facilities, a urine pregnancy test is required prior to dispensing the pills to rule out an existing pregnancy. There is some controversy about the need to do this, since there is no evidence to suggest that OCs used in this manner affect early fetal development and the dose as prescribed would not disrupt a previously undetected pregnancy. A progestin-only EC kit was FDA approved in 1999 and contains 2 tablets, each with 0.75?mg of levonorgestrel. Nausea and vomiting are uncommon side effects, and in a recent comparison levonorgestrel proved more effective at preventing pregnancy. Mifepristone (RU-486) is a highly effective EC method with a nearly 0% failure rate; however, it functions as an abortifacient and its use is highly controversial. A 2-wk follow-up appointment is recommended following any of the methods to determine the effectiveness of treatment and to diagnose a possible early pregnancy. The visit also provides an opportunity to counsel the adolescent, explore the situation leading up to the unprotected intercourse, test for STDs, and initiate continuing contraception when appropriate.

108.6 Intrauterine Devices

Intrauterine devices (IUDs) are small, flexible, plastic objects introduced into the uterine cavity through the cervix. They differ in size, shape, and the presence or absence of pharmacologically active substances (e.g., copper or progesterone). The mechanism of action of IUDs is uncertain, although they render the endometrium unsuitable for implantation by inducing a local polymorphonuclear leukocyte response, production of prostaglandins E_2 and F_2 , and stimulation of uterine contractility. They are effective in preventing pregnancy in 97–99% of women. Young patients and those with multiple sexual partners are at increased risk of infection, and the prescription of an IUD to teenagers who require passive contraception should be limited to the method of last resort.

Chapter 109 - Pregnancy

Renée R. Jenkins

Sexual activity at an early age coupled with nonuse or improper use of contraceptives contributes to a disproportionately high rate of teenage pregnancy in the United States when compared

with other industrialized nations. By virtue of the trajectory of early sexual activity to early unintended pregnancy, the risk and protective factors are similar. Factors associated with childbearing as the outcome for teenage pregnancy, however, are strongly linked to poverty and the absence of opportunity for other life choices.

Epidemiology.

The estimated number of pregnancies in adolescent women fell to approximately 479,067 in 2000. The birthrate of 48.7 births/1,000 for women aged 15–19 yr is the lowest level reported in the United States since 1940 (Fig. 109–1). When considered in the context of the number of sexually active adolescents, the decline is impressive. First births to teens make up the substantial proportion of the reduction, with second births remaining stable since 1996. Most of the pregnancies are unintended, and a significant proportion of young women voluntarily terminate the pregnancy. Forty-one per cent of girls younger than 15 yr of age and 29.1% of 15–19 yr olds elected abortion in 1997, although the overall rates of abortion are also down. Internationally, the United States leads all other industrialized countries in the teen birthrate, and although the birthrate is declining, the drop is less steep than the declines in other developed countries (Fig. 109–2).

Etiology.

As with early initiation of intercourse, the factors associated with pregnancy are multifactorial at the individual, family, and environmental levels (Chapter 99). The sexually active female teenager's success in avoiding unintended pregnancy is determined by her ability to use an effective contraceptive method consistently. Young teenagers are likely to be less deliberative and logical about their sexual decisions than are adults, and their sexual activity is likely to be sporadic and coercive, factors contributing to inconsistent contraceptive use and greater risk of pregnancy. Once the pregnancy has occurred, the decision to bear a child, keep or place the child for adoption, or terminate the pregnancy is influenced again by multiple issues. Parents, most often mothers, have a tremendous influence on what the adolescent decides to do. Friends and sexual partners

Figure 109-1 Number of births and birthrates for teenagers 15–19 years: United States, 1940–2000. (Adapted from *National Vital Statistics Report*, vol 49, no 19, September 25, 2001.)

play a lesser role. Better employment prospects as well as other lifestyle benefits are associated with lowered probability of childbearing. A young woman's attitude toward abortion is the strongest factor associated with that choice. Access to abortion services and individual factors such as high self-esteem and aspirations for further education play a role. Adoption appears to be an option less often considered currently and is associated with younger age, expectations of fewer children and, less often, receiving welfare support prior to pregnancy. Marriage following a first teenager birth is least likely to occur in young teenagers and teenagers with less than a high school education and more likely to occur in some cultural groups, such as Hispanic teens. Overall, adoption and marriage are choices less often selected by pregnant adolescents.

Clinical Manifestations.

Adolescents may experience the traditional symptoms of pregnancy, that is, morning sickness, swollen tender breasts, weight gain, and amenorrhea; however, the presentation is often more vague. Headache, fatigue, abdominal pain, and scanty or irregular menses are common presenting symptoms.

Denial of sexual activity and menstrual irregularity should not preclude the diagnosis in face of other clinical or historical information. An unanticipated request for a complete check-up or a visit for contraception may uncover a suspected pregnancy. Pregnancy is still the most common diagnosis when an adolescent presents with secondary amenorrhea.

Diagnosis.

On physical examination, the findings of an enlarged uterus, cervical cyanosis (Chadwick sign), a soft uterus (Hegar sign), or a soft cervix (Goodell sign) are highly suggestive of an intrauterine pregnancy. A confirmatory pregnancy test is always recommended. The most commonly used method is a qualitative measurement of the s-subunit for human chorionic gonadotropin (hCG) by blood or urine. The results are positive in 98% of women within 7 days after implantation. The most sensitive test is a quantitative ß-hCG radioimmunoassay, in which results are reliable within 7 days after fertilization. This test is more expensive and less likely to be used under routine circumstances. Evaluation for a possible ectopic pregnancy, a retained placenta following an abortion, or a molar pregnancy are some of its more common uses. Urine pregnancy tests are the enzyme-linked immunosorbent assay type using highly specific monoclonal antibodies to the s-subunit of hCG. These tests may be positive as early as 3 to 4 days after implantation. One health department study reported 28% of adolescents requesting pregnancy tests had already performed

home pregnancy tests prior to the visit. These tests are most often of lower sensitivity and specificity than tests used in the office and should be repeated with more reliable tests before proceeding with clinical management.

Treatment.

Confidentiality and privacy are key components of counseling the adolescent in whom pregnancy is suspected. The younger the adolescent, the greater should be the concern that the sexual activity may have been coercive. Special sensitivity is required to explore this issue with the adolescent as is knowledge of proper procedures for enlisting help for the adolescent and reporting suspected abuse. If the adolescent's pregnancy test result is negative, it is prudent to repeat the test in 2 wk. If the repeat test result is negative, the opportunity to counsel the adolescent and provide the appropriate intervention should be seized. If the adolescent is pregnant, the options available to manage the pregnancy should be presented and discussed in the context of her family, and her individual situation. Adolescents should be encouraged to include parents fully in the discussion of their options. When parents are not available or the adolescent is resistant to their initial involvement, the adolescent is urged to involve a trusted adult—for example, a relative or counselor—in the decision-making process. Follow-up is

Figure 109-2 Teenage birthrates declined less steeply in the United States than in other developed countries between 1970 and 2000. (Adapted from Alan Guttmacher Institute: *Can More Progress Be Made? Teenage Sexual and Reproductive Behavior in Developed Countries.* Executive Summary, 2001, p 2.)

necessary to ensure this involvement, given the possibility that denial, fear, and indecisiveness may delay the adolescent's seeking adult support.

Risks and Consequences of Teenage Childbearing.

Adverse outcomes for pregnant teenagers are reduced significantly by early prenatal care. Twenty per cent of teenagers younger than age 15 yr and 12% of all teenagers are likely to receive only third trimester care or no care at all prior to delivery. Adolescent parenting has implications for the adolescent mother, father, and child. When adolescent mothers are compared with their peers, they are less likely to complete high school and have steady employment and are more likely to be on public assistance at some point in their lives and to be in unstable marriages. Infants born to adolescent mothers younger than 15 yr old are at greater risk for low birthweight. The children of adolescents experience more problems in school, showing difficulties with cognitive functioning, and have an increased risk of experiencing an accident within the home and of being hospitalized before 5 yr of age. Men who father the children of adolescent mothers are usually 2–3 yr older than the mother and often not teenagers themselves. However, fathers who are adolescents often suffer the same social and economic risks of the teenage mother, with many fewer resources and programs to assist them. Some controversy exists as to whether the social and economic outcomes are a function of maternal age or maternal and family poverty.

Prevention.

The reductions in teenage pregnancy rates, although limited, have been attributed to an increase in contraceptive use at first intercourse and a decrease in sexual activity. Although researchers are still actively seeking successful teenage pregnancy interventions, the multifactorial nature of the issue suggests a multilevel approach. On the individual level, postponing sexual involvement until psychosocial maturity guides a more responsible preventive behavior is the principle underlying a number of successful programs. The pediatrician contributes to this strategy through anticipatory guidance. The next level is to provide birth control counseling to adolescents who are sexually active to protect against pregnancy and sexually transmitted disease. On the community level, there needs to be improved access to protective medical measures, with attention to age-appropriate health care delivery models, and the removal of financial barriers to these services. At a societal level, corroborated by the international experience, improved economic opportunities and the enhancement of life options for young women and young men play a pivotal role in achieving positive outcomes related to teenage sexual behavior and the risk of pregnancy and parenthood.

Chapter 110 - Sexually Transmitted Diseases

Renée R. Jenkins

The behavioral and physiologic characteristics of adolescence predispose sexually active adolescents to the increased acquisition and adverse consequences of sexually transmitted diseases (STDs). When controlled for sexual activity, age-specific rates of many STDs are highest among sexually experienced adolescents. For STD pathogens, intimate sexual contact is the common mode of transmission; however, the clinical expression can be listed according to STD syndromes based on a constellation of clinical signs and symptoms. Different microorganisms are responsible for similar symptoms. Almost all STD pathogens can also infect an adolescent without manifesting any clinical symptoms. The approach to prevention and control of these diseases lies in education, screening, and early diagnosis and treatment. (See chapters discussing specific microorganisms in Part XVI .)

Etiology.

The risk of contracting an STD exists in any adolescent who has had sexual intercourse. The risk is increased for specific STDs when certain factors exist. The younger the adolescent at the time of initiation of sexual activity, the higher the risk. Inadequate time to develop decision-making and cognitive skills as well as biologic status contribute to this susceptibility. The use of drugs and alcohol removes inhibitions and contributes to unplanned and unprotected sexual activity. Intravenous drug

use, sex with homosexual or bisexual males, and a history of exchanging sex for food, shelter, money, or drugs are all associated with increasing risk for human immunodeficiency virus (HIV) and other serious STDs. Exposure to uncommon sexual pathogens is increased with anal sex. Sex with more than one partner in 6 mo and failure to use condoms consistently are behaviors for which educational interventions may have some impact. Adolescents who are victims of sexual abuse or rape may not consider themselves “sexually active,” given the context of the encounter, and need reassurance, protection, and appropriate intervention when

these circumstances are uncovered.

Epidemiology.

Adolescents and young adults younger than 25 yr of age have the highest reported prevalence of gonorrheal and chlamydial infection. Rates for gonorrhea in the United States are highest for 15–19 yr old females and 20–24 yr old males. They have dropped from 724.7/100,000 to 715.6/100,000 for females and 373/100,000 to 327/100,000 for males, aged 15–19 yr, for 2000 as compared with 1996. For the 20–24 yr olds, the rates have increased during the same period, 21% higher for females and 10.7% higher for males. Chlamydia is the most common bacterial STD in the United States. The year 2000 is the first year that all 50 states and the District of Columbia reported chlamydial infections to the CDC. The rates show a pattern similar to that of gonococcal infections, with the highest rates in 15–19 yr old females and 20–24 yr old males. After peaking in 1990, the rates for primary and secondary syphilis are declining for all ages. Pelvic inflammatory disease (PID) rates are highest in females aged 15–25 yr when compared with older women. AIDS, but not HIV, is reportable in the United States, giving a somewhat skewed perception of a lower rate of infection in adolescents. In 2000, 342 adolescents with AIDS were reported nationwide, whereas 879 adolescents with HIV were reported from the 34 areas that conduct name-based confidential HIV infection surveillance. The lengthy incubation period coupled with a range of smaller seroprevalence studies underscore the serious risk of HIV disease and the impact of its limited reporting for this population.

Pathogenesis.

During puberty, increasing levels of estrogen cause the vaginal epithelium to thicken and cornify and the cellular glycogen content to rise, the latter causing vaginal pH to fall. These changes increase the resistance of the vaginal epithelium to penetration by certain organisms (including *Gonococcus*) and increase the susceptibility to others (e.g., *Candida albicans* and *Trichomonas).* The transformation of the vaginal cells leaves columnar cells on the ectocervix, forming a border of the two cell types on the ectocervix, known as the squamocolumnar junction. The appearance is referred to as *ectopy.* With maturation, this tissue involutes. Prior to involution, it represents a unique vulnerability to infection for adolescent females. A 15 yr old sexually active girl with endocervical colonization has a 1:8 chance of developing PID as compared to the 1:80 chance for a 24 yr old. As a result of these physiologic changes, gonococcal infection becomes primarily cervical and susceptibility to ascending infection is greatest during menses, when the pH is 6.8–7.0. Menstruation in an adolescent with endocervical colonization presents a risk factor for the development of PID.

Clinical Manifestations.

STD syndromes are generally characterized by the location of the manifestation (vaginitis) or the type of lesion (genital ulcer). In addition, certain constellations of presenting symptoms suggest the inclusion of a possible STD in the differential diagnosis. The syndromes and the conditions suggestive of STDs are listed in Box 110–1 .

URETHRITIS.

Urethritis is an inflammation of the urethra classically presenting as a urethral discharge or dysuria, or both. Urgency, frequency of urination, erythema of the urethral meatus, and scrotal pain are less common clinical presentations.

Box 110-1. Sexually Transmitted Disease Clinical Syndromes

SEXUALLY TRANSMITTED DISEASE SYNDROMES

- Urethritis
- Epididymitis
- Vaginitis (vulvitis)
- Cervicitis
- Pelvic inflammatory disease
- Genital ulcer disease
- Genital lesions and ectoparasites

CONDITIONS SUGGESTIVE OF SEXUALLY TRANSMITTED DISEASE

- Lower abdominal pain (female)
- Scrotal swelling and pain
- Arthritis
- Exanthem, alopecia
- Pharyngitis
- Conjunctivitis
- Hepatitis, perihepatitis
- Local and generalized lymphadenitis
- Proctitis

Hepatitis, perihepatitis

Local and generalized lymphadenitis

Proctitis

Asymptomatic or minimally symptomatic presentations are common in males. Adolescent males, in particular, are likely to ignore symptoms that improve spontaneously or sometimes ignore obvious physical signs. Consequently, the genital examination should be thorough, including retraction of the foreskin in uncircumcised males, regardless of the denial of symptoms by the adolescent. Examining a patient prior to a urinary void is an important factor in observing a minimally symptomatic discharge. *C. trachomatis* and *Neisseria gonorrhoeae* are the most common pathogens. *Ureaplasma urealyticum* and *Mycoplasma genitalium* are still considered potential pathogens in nongonococcal urethritis, when *Chlamydia* cannot be confirmed. Diagnostic tests for these pathogens are not readily available. *T. vaginalis* and herpes simplex virus (HSV) are considered in the differential diagnosis when nongonococcal urethritis is resistant to treatment. There are classic descriptions of discharges, associating pathogens with color and consistency, e.g., yellow-green purulent discharge for gonococci and white mucopurulent discharge for chlamydia; however, co-infection and other factors can alter the appearance of discharges. Co-infection with gonococcal and chlamydial urethritis is reported in more than 25% of men with urethritis. Consequently, laboratory evaluation is key to determining the involved pathogens.

EPIDIDYMITIS.

The inflammation of the epididymis in adolescent males, unlike that in adult males, is most often associated with an STD. The same pathogens associated with urethritis are prevalent. The presentation of scrotal swelling and tenderness, associated with the history of a spontaneously resolving urethral discharge, constitute the presumptive diagnosis of epididymitis. A urethral discharge may still be present at the time of examination. Males who practice insertive anal intercourse are also vulnerable to *Escherichia coli* infection.

VAGINITIS (VULVITIS).

Vaginitis is a superficial infection of the vaginal mucosa frequently presenting as a vaginal discharge, with or without vulvar involvement (see Chapter 541). Pruritus and the presence of an odor help differentiate the cause of the infection. Colonization without infection, as in bacterial vaginosis, can also present as a vaginal discharge. Although bacterial vaginosis is no longer categorized strictly as an STD, sexual activity is associated with increased frequency of vaginosis. Trichomoniasis and candidiasis, together with bacterial vaginosis, are the predominant diseases associated with vaginal discharge. The clinical observations of the color, consistency (frothy, floccular, homogeneous), odor, extent of vulvar involvement, and cervical changes lead one to a presumptive

diagnosis. However, laboratory confirmation is recommended in determining the presence of one or more infections that may present in an uncharacteristic manner. The differential diagnosis for vaginitis with the classic presentations is presented in Figure 110–1 .

CERVICITIS.

The inflammatory process in cervicitis involves the deeper structures in the mucous membrane of the cervix uteri. Vaginal discharge can be a manifestation of cervicitis, if the cervical discharge is profuse. Less subtle clinical manifestations of cervicitis are irregular or postcoital bleeding, mucopurulent discharge from the os, and a friable cervix. The cervical changes associated with cervicitis must be distinguished from cervical ectopy in the younger adolescent to avoid the overdiagnosis of inflammation. The pathogens associated most commonly with cervicitis are *C. trachomatis* and *N. gonorrhoeae,* which are responsible for about 50–60% of cases. HSV is a less common pathogen associated with ulcerative and necrotic lesions on the cervix.

PELVIC INFLAMMATORY DISEASE.

A spectrum of inflammatory disorders of the upper genital tract in females is encompassed under the diagnosis of PID. The spectrum includes endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis, usually in combination rather than as separate entities. *N. gonorrhoeae* and *C. trachomatis* predominate as the involved pathogenic organisms in younger adolescents; maturation and recurrent disease increase the appearance of other anaerobic and aerobic bacteria such as *Mycoplasma hominis,* group B streptococci, streptococci, *Peptostreptococcus* spp., *Gardnerella vaginalis, E. coli,* and various *Bacteroides* spp.

The clinical diagnosis of PID is based on the minimal criteria of lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness in a sexually active female adolescent with no other causes for illness. Although embarrassment may preclude an adolescent's honest answer regarding prior sexual activity, this history should not preclude gathering of evidence

Figure 110-1 Differential diagnosis of vaginitis. (From Emans SJ, Laufer MR, Goldstein DP [editors]: *Pediatric and Adolescent Gynecology, 4th ed.* Philadelphia, Lippincott-Raven, 1998, p 427.)

for this possible diagnosis. The presence of a recent increase in dysmenorrhea, onset of symptoms following menses, fever, urinary symptoms, abnormal vaginal bleeding, and abnormal vaginal discharge add support to the clinical diagnosis.

GENITAL ULCER SYNDROMES.

An ulcerative lesion in a mucosal area exposed to sexual contact is the unifying characteristic of diseases associated with these syndromes. These lesions are most commonly seen on the penis and vulva, but also occur on oral and rectal mucosa

depending on the sexual practices of the adolescent. HSV, *Treponema pallidum* (syphilis), and *Haemophilus ducreyi* (chancroid) are the organisms associated with genital ulcer syndromes. Although the initial herpetic lesion is a vesicle, by the time the patient presents clinically, the vesicle most often has ruptured spontaneously, leaving a shallow, painful ulcer. Of these syndromes, syphilis and chancroid are less common in adolescents than in adults. HSV-2 predominates as the pathogen in this age group, with an increasing incidence of HSV-1 recovered in genital lesions, especially in women. Clinical characteristics differentiating the lesions are presented in Table 110–1 , along with the required laboratory diagnosis to identify the causative agent accurately.

GENITAL LESIONS AND ECTOPARASITES.

Lesions that present as outgrowths on the surface of the epithelium and other limited epidermal lesions are included under this categorization of syndromes. Human papillomavirus with its association to cervical cancer causes the most concern for the long-term outcome for individuals infected during adolescence (see Chapter 243). Molluscum contagiosum and condyloma lata associated with secondary syphilis complete this classification of syndromes.

HUMAN IMMUNODEFICIENCY VIRUS DISEASE AND HEPATITIS B.

HIV and hepatitis B diseases present as asymptomatic, unexpected occurrences in most infected adolescents. Risk factors identified in the history are much more likely to

TABLE 110-1 -- **Signs, Symptoms, and Presumptive and Definitive Diagnoses of Genital Ulcers**

Signs/Symptoms	Herpes Simplex Virus	Syphilis (Primary)	Chancroid
Ulcers	Vesicles rupture to form shallow ulcers	Ulcer with well-demarcated indurated borders and a clean base (chancre)	Unindurated and undermined borders and a purulent base
Painful	Painful	Painless*	Painful
Number of lesions	Usually multiple	Usually single	Multiple
Inguinal lymphadenopathy	First-time infections may cause constitutional symptoms and lymphadenopathy	Usually mild and minimally tender	Unilateral or bilateral painful adenopathy in >50% Inguinal bubo formation and rupture may occur
Presumptive diagnosis	Typical lesions plus any of the following: a previously known outbreak, a positive Tzanck smear of lesion scraping, exclusion of other causes of ulcers, or a fourfold increase in acute and convalescent antibody titers (in a first-time infection)	Early syphilis: a typical chancre plus a reactive nontreponemal test (RPR, VDRL) and no history of syphilis or a fourfold increase in a quantitative nontreponemal test in a person with a history of syphilis	Exclusion of other causes of ulcers in the presence of (1) typical ulcers and lymphadenopathy, (2) a typical Gram stain and a history of contact with a high-risk individual (prostitute) or living in an endemic area
Definitive diagnosis	Detection of HSV by culture or nonculture methods (DFA) from ulcer scraping or aspiration of vesicle fluid	Identification *T. pallidum*, from a chancre or lymph node aspirate, on dark-field microscopy or by DFA	Detection of *H. ducreyi* by culture

DFA = direct fluorescent antibody; HSV = herpes simplex virus; RPR = rapid plasma reagin; VDRL = Venereal Disease Research Laboratory.

result in suspicion of disease, leading to the appropriate laboratory screening, than are clinical manifestations in this age group.

Diagnosis

ASYMPTOMATIC PATIENTS.

Health screening guidelines (see Chapter 100) recommend testing for STDs in asymptomatic patients on an annual basis. Asymptomatic infections with viral pathogens, such as HIV, HSV, and hepatitis B, are the most common presentations for these diseases, whereas asymptomatic infections for chlamydial infection and gonorrhea range from 17–56% and 2–33%, respectively. Adolescent males are more likely to be asymptomatic with chlamydia, whereas adolescent females have a higher rate of asymptomatic gonococcal infections. Urethritis can be documented in an asymptomatic male with a positive leukocyte esterase test on first voided specimen with >10 WBCs per high power field or >5 WBCs per oil immersion field on a Gram stain of urethral secretions. Nucleic acid amplification tests (NAATs) such as polymerase chain reaction, ligase chain reaction, and strand displacement assay are highly recommended for chlamydia screening. Cultures are still preferred for *N. gonorhoeae* when holding and transport conditions are adequate to maintain specimen viability. NAATs are not highly recommended for testing rectal swabs. Availability and cost may limit the use of these new tests in some communities. Indirect tests should not be substituted for cultures for STD screening in suspected sexual abuse cases because of the possibility of false-positive results from indirect tests. Advances in HIV testing have also increased opportunities for screening asymptomatic adolescents. Rapid HIV testing with the availability of results in 10–60?min can be useful in settings in which the likelihood of adolescents returning for their results is low, although this does not eliminate the need for confirmatory testing. Based on the preceding observations, the recommendations for screening sexually active adolescents are listed in Table 100–1 .

SYMPTOMATIC PATIENTS.

Based on the clinical presentation, further evaluations may be needed to identify the causative agent of the syndrome accurately. For urethritis, a Gram stain when a urethral discharge is present confirms the diagnosis of gonorrhea at the time of the presenting symptom. The wet mount is useful in determining the possible pathogen causing a vaginal discharge (see Fig. 110–1). The definitive diagnosis of PID is difficult based on clinical findings alone, and even with an experienced clinician, one third of women are diagnosed incorrectly. In addition to an elevated temperature (>101°F or >38.3°C) and an abnormal cervical or vaginal discharge, the finding of an elevated erythrocyte sedimentation rate or an elevated C-reactive protein level in combination with confirmative laboratory documentation of *N. gonorrhoeae* or *C. trachomatis* is recommended to avoid incorrect diagnosis and inappropriate management. Imaging techniques demonstrating thickened fluid-filled fallopian tubes with or without free pelvic fluid or a tubo-ovarian complex are definite criteria. Direct visualization through the laparoscopic technique with cultures from the fallopian tube, while infrequently performed in the United States, is the gold standard for definitive diagnosis. The HSV direct fluorescent antibody test or the herpes culture is readily available in most clinical settings to help determine the pathogen in genital ulcer syndromes. Dark-field microscopy and fluorescent antibody tests to confirm syphilis are less frequently available, with most clinicians relying on serologic confirmation. Tests to confirm the diagnosis of human papillomavirus are discussed in Chapter 243 , although Papanicolaou smear often reveals the first evidence of vaginal or cervical involvement in adolescents. Symptomatic or asymptomatic adolescents with STDs should be screened for HIV.

DIFFERENTIAL DIAGNOSES.

The differential diagnoses are particular to each of the clinical syndromes. *Reiter's syndrome* is considered an autoimmune response to an STD or enteric pathogen and is characterized by arthritis, nonbacterial urethritis or cervicitis, conjunctivitis, and mucocutaneous lesions. The urinary symptoms associated with urethritis mimic a urinary tract infection, a condition much less common than an STD in adolescent males. Testicular torsion, the main differential diagnosis to consider in scrotal pain, constitutes a surgical emergency, although trauma is a more common occurrence, especially in adolescent males involved in contact sports (see Chapters 538 and 681). Vaginitis and vulvar irritation can result from a foreign body or chemical irritant, for example, bubble bath or spermicide.

The differential diagnosis for PID, presenting as acute lower abdominal pain, is extensive, involving the gastrointestinal, reproductive, and urinary systems. The most emergent differential diagnosis in a sexually active adolescent is to distinguish PID from appendicitis or an ectopic pregnancy, which both require surgical intervention. Given the complexity of the management approach, clinical practice guidelines are extremely useful in moving swiftly and logically to the correct diagnosis (Box 110–2 (Box Not Available)). Most of the conditions in the differential diagnosis of genital ulcerative lesions

Box 110-2. Uncomplicated Pelvic Inflammatory Disease Clinical Practice Guideline Inclusion Checklist
(Not Available)
From Emans SJH, Laufer MR, Goldstein DP (editors): Pediatric and Adolescent Gynecology, 4th ed. Philadelphia, Lippincott-Raven, 1998, p 480.

rarely occur in teenagers in the United States (i.e., lymphogranuloma venereum, granuloma inguinale); however, trauma is a common cause that can be detected with a careful history.

Treatment.

See Part XVI for chapters on the treatment of specific microorganisms. Treatment regimens using over-the-counter products for *Candida* vaginitis, genital warts, and pediculosis reduce financial and access barriers to rapid treatment for adolescents, but there are potential risks for inappropriate self-treatment and complications from untreated more serious infections that must be considered before using this approach. Minimizing noncompliance with treatment, finding and treating the sexual partner, addressing prevention and contraceptive issues, and making every effort to preserve fertility are additional physician responsibilities. The latter often requires intensive parenteral therapy for PID.

Diagnosis and therapy are often necessarily carried out within the context of a confidential relationship between the physician and the patient. Therefore, the need to report certain sexually transmitted diseases to health department authorities should be clarified at the outset. Most health departments will not violate confidentiality, if assured that treatment and case finding have been accomplished and that the patient can be expected to follow through in a responsible, mature manner.

Prevention.

The prevention messages to be communicated to adolescents regarding the avoidance of STDs are in direct contrast to the known risk factors for contracting the disease: (1) maintaining a healthier sexual behavior, (2) using barrier methods, (3) adopting healthy medical care–seeking behavior, (4) complying with management instruction, and (5) ensuring examination of sexual partners. The elements of maintaining healthier sexual behavior include postponing sexual behavior until *at least* 2–3 yr after menarche, limiting the number of sexual partners, eliciting information about a partner's STD status, inspecting the genitals of sexual partners, and abstaining from sex if STD symptoms develop. The upsurge in sexuality education as a result of the HIV epidemic may have played some role in the increased use of condoms in adolescents (see Chapter 108).

Chapter 111 - Chronic Fatigue Syndrome

Hal B. Jenson

Numerous terms (e.g., chronic mononucleosis, chronic Epstein-Barr virus [EBV] infection, and immune dysfunction syndrome) have been applied to the syndrome of easy fatigability associated with mild to debilitating somatic symptoms. This syndrome was formally defined by the Centers for Disease Control and Prevention (CDC) in 1988 as chronic fatigue syndrome because it is fatigue or profound tiredness that is the principal and invariable physical symptom, associated with a variety of physical symptoms and marked and prolonged functional impairment. Chronic fatigue syndrome is neither a new disease nor the result of enhanced appreciation of previously unrecognized clinical illness and is not caused by an identifiable infectious agent, although the differential diagnosis includes many infectious and noninfectious diseases. It is not a single disease with consistent physiologic or pathologic abnormalities but is the subjective experience of symptoms that encompass various clinical conditions of somatic, psychologic, and mixed causes. Current understanding of this condition is largely from studies among adults and adolescents, with limited descriptions of chronic fatigue syndrome in young children.

Epidemiology.

Chronic fatigue is a common presenting symptom of adolescents and adults. Approximately 20% of adults in primary care clinics or in surveys complain of chronic fatigue; the incidence in children is unknown. Prevalence rates vary significantly, but chronic fatigue syndrome is encountered in all patient populations. Most patients diagnosed with chronic fatigue syndrome are white, 25–45 yr of age, well educated, high achievers, and in above-average income brackets. These epidemiologic observations may be artifactual because assertive individuals may be less likely to accept being told by their physician

that there is nothing physically wrong and are more likely to insist on referral to medical specialists. Women constitute 75% of adult patients. The minimum prevalence in the United States is estimated to be 4–10 cases/100,000 adults 18 yr of age and older. Most cases of chronic fatigue syndrome are sporadic and are not associated with secondary cases. No evidence shows that chronic fatigue syndrome can be transmitted from person to person, in utero to a fetus, or via blood products.

Pathogenesis.

The cause of chronic fatigue syndrome is unknown. There is no evidence to support the hypothesis that infection with a known or new virus is the primary cause of the symptoms of chronic fatigue syndrome. Some patients correlate the onset of chronic fatigue syndrome with a history of a virus-like illness such as infectious mononucleosis (EBV) or influenza. In many cases the clinical symptoms of depression, such as fatigue, lack of energy and interest, and inability to concentrate, merge with or are intensified by the weakness often found during convalescence from a systemic infectious disease, resulting in disabling fatigue. Persistent fatigue after an otherwise uncomplicated primary infection is well recognized with many acute infections, especially infectious mononucleosis and influenza. In vulnerable persons, symptoms of fatigue and exhaustion may last for months to a few years and may be accompanied by signs of depression.

Approximately half of adult and adolescent patients fulfill criteria for co-morbid psychiatric disorders, mainly anxiety and depressive disorders. Personality may have special relevance to the predisposition, precipitation, and perpetuation of chronic fatigue. Several studies of convalescence after acute systemic infections support the view that symptomatic recovery is critically dependent on the emotional state and attitude of the individual. Individuals with a propensity to succumb to illness are more likely to respond to acute infection with fatigue and depression-like symptoms than are individuals who do not have such vulnerability.

Up to one half of patients with chronic fatigue syndrome have a concomitant orthostatic intolerance syndrome of circulatory dysfunction including neurally mediated hypotension, instantaneous orthostatic hypotension, and postural tachycardia syndrome. The lightheadedness among patients with chronic fatigue syndrome and orthostatic intolerance appears related to decreased cerebral oxygenated hemoglobin, although factors other than simply reduced cerebral blood flow appear to be operative. Quick control systems of cerebral vasoconstriction such as autonomic reflexes and inhibition of nitric oxide, and increased oxygen consumption by brain tissue have been postulated.

Several diverse and sometimes conflicting in vitro immunologic abnormalities (e.g., hypo- or hypergammaglobulinemia, immunoglobulin subclass deficiencies, elevated levels of circulating immune complexes, mild increased helper/suppressor lymphocyte ratios, natural killer cell dysfunction, monocyte dysfunction) have been reported in patients with chronic fatigue syndrome. A history of food, inhalant, or drug allergy is reported by approximately 67% of patients. No characteristic profile of immune dysfunction has been identified, and the magnitude of the immune abnormalities described is small and does not correlate with the severity of clinical symptoms.

Clinical Manifestations.

The symptoms of chronic fatigue syndrome are protean, with a spectrum of

gradation from subtle to debilitating. Although the perception of the primary symptom of fatigue is subjective and undoubtedly varies from individual to individual, fatigue as a symptom should not be dismissed as a minor ailment. The syndrome is characterized by numerous somatic complaints of at least 6 mo to several years' duration associated with significant impairment (below 50% of normal) of the work or school schedule, activities of daily living, exercise tolerance, and interpersonal relationships. Fatigue is generally manifested as lassitude, profound tiredness, weakness, intolerance to exertion with easy fatigability, significant daytime sleeping, and general malaise. Nocturnal sleeping is usually unchanged and does not differ from that of unaffected individuals. Myalgias and low-grade fever in 50–95% of cases characteristically accompany fatigue. Headache and sore throat are common. A multitude of other physical symptoms (e.g., chest palpitations, visual blurring, nausea, dizziness, arthralgias, paresthesias, dry eyes and mouth, diarrhea, cough, night sweats, tender lymphadenopathy, rash) have been reported in 30–60% of cases. Emphasis on one particular physical symptom other than the constitutional symptoms of malaise and fatigability is somewhat uncommon and should prompt further investigation. Weight loss is uncommon in chronic fatigue syndrome. Symptoms of cognitive dysfunction are common and include confusion, difficulty in concentrating, impaired thinking, and forgetfulness. Adult patients often judge these as among the most debilitating symptoms.

Most patients diagnosed with chronic fatigue syndrome relate an abrupt onset to their symptoms, often as part of an initial virus-like illness characterized by low-grade fever accompanied by sore throat and cough. Less frequently, the initial symptoms indicate gastrointestinal tract involvement with nausea and diarrhea. Myalgia is a common symptom.

Symptoms in children appear to be similar to those in adolescents and adults. School absenteeism is a major problem. In a small retrospective study of 23 patients with a median age of 14 yr and a median duration of symptoms of 6 mo, 67% missed 2 wk or more of school and 33% required a home tutor.

Abnormal physical examination findings are conspicuously absent and provide reassurance to both the patient and the physician. Orthostatic intolerance with abnormal heart rate and blood pressure responses to tilt-table testing is common, and impaired cerebral oxygenation measured by near infrared spectroscopy has been documented.

Diagnosis.

There are no pathognomonic signs or diagnostic tests for chronic fatigue syndrome; the diagnosis is a clinically defined condition based on inclusionary and exclusionary criteria (Fig. 111–1). Chronic fatigue syndrome in adults is a diagnostic subset of chronic fatigue, a broader category defined as unexplained fatigue of more than 6 mo, which in turn is a subset of prolonged fatigue, which is defined as fatigue lasting more than 1 mo. The diagnostic criteria are applicable to children, with the exception that the required 6 mo duration is too long to be applied to children.

Chronic fatigue syndrome is difficult to diagnose in children, who have trouble describing their symptoms and articulating their concerns. As with any chronic illness in childhood, careful attention must be directed to the family dynamics to identify and resolve family problems or psychopathology that may be contributing to a child's perceptions of his or her symptoms. The diagnosis of chronic fatigue syndrome in a child should be contemplated with caution. Applying the label of chronic fatigue syndrome may delay the diagnosis of a treatable medical illness, avoid the detection of psychologic problems or family dysfunction, and perpetuate inappropriate illness behaviors that may have a profound effect on the child's psychosocial development. Most patients, including children, with chronic fatigue syndrome attribute their symptoms primarily to physical causes and disregard psychologic influences.

The diagnosis of chronic fatigue syndrome can be established only after alternative medical and psychiatric causes of fatigue, many of which are treatable, have been excluded. These include any medical condition that may explain the presence of chronic fatigue, such as untreated hypothyroidism, sleep apnea, narcolepsy, an adverse effect of medication, or severe obesity as defined by a body mass index [body mass index = weight in kg/ (height in meters)^2] of 45 or greater. A previously diagnosed

Figure 111-1 The clinical evaluation and classification of unexplained chronic fatigue. The case definition for chronic fatigue syndrome was proposed by the Centers for Disease Control and Prevention in 1988 (Holmes GP, Kaplan JE, Gantz NM, et al: Chronic fatigue syndrome: A working case definition. *Ann Intern Med* 1988;108: 387–9) and refined and simplified by an international working group in 1994 (Fukuda K, Straus SE, Hickie I, et al: The chronic fatigue syndrome: A comprehensive approach to its definition and study. *Ann Intern Med* 1994;121: 953–9).

medical condition with uncertain resolution that may explain chronic fatigue should be clarified, such as unresolved cases of hepatitis B or C virus infection. Chronic fatigue syndrome should not be diagnosed in persons with prior diagnoses of a major depressive disorder with psychotic or melancholic features; bipolar affective disorders; schizophrenia of any subtype; delusional disorders of any subtype; dementias of any subtype; anorexia nervosa; bulimia nervosa; or alcohol or other substance abuse within 2 yr before the onset of the chronic fatigue or at any time afterward.

Fibromyalgia (fibrositis) is a relatively common rheumatic syndrome characterized by symptoms of chronic fatigue syndrome but with widespread musculoskeletal pain in addition to numerous specific tender point sites (see Chapter 158). Fibromyalgia may represent a subset of patients with chronic fatigue syndrome characterized by heightened musculoskeletal symptoms.

Although evaluation of each patient should be individualized, initial laboratory evaluation should be limited to screening laboratory tests to provide reassurance of the lack of significant organic dysfunction (see Fig. 111–1). Further tests should be directed primarily toward excluding treatable diseases that may be suggested by the symptoms or physical findings that are present. Diagnostic evaluation of chronic fatigue should include psychologic evaluation for anxiety and depression disorders, which should precede exhaustive searches for organic causes.

Treatment.

Development of definitive treatment for chronic fatigue syndrome awaits delineation of the causes of the symptoms. No specific therapeutic agents are recommended. No data suggest relief of symptoms or cure of chronic fatigue syndrome by dietary or vitamin supplements. Low-dose hydrocortisone is associated with some improvement in symptoms, but the associated adrenal suppression argues against its use. Therapy should be directed toward emotional support for patients and their families, relief of symptoms, and minimizing unnecessary and misleading diagnostic and therapeutic tests. This may include a combination of restoration of a normal sleep pattern, rehabilitation strategies including exercise for fatigue, and optimism. Psychologic or psychiatric intervention is a principal component of treatment if a co-morbid psychiatric disorder is present.

Patients with severe limitation of activity should be started on a schedule of graded remobilization, determined by individual tolerance and, if warranted, physical therapy leading to a regular regimen of moderate exercise. Complete bed rest and lack of exercise only perpetuate immobility and lead to deconditioning; rapid remobilization, for whatever reason, usually exacerbates symptoms and should be avoided. Return to school should also be initiated gradually but systematically to resume normal attendance and socialization. Home tutoring may be an interim alternative. Patients and their families should clearly understand that there is no evidence that activity harms patients with chronic fatigue syndrome. Continued empathy and support by

the treating physician are important in maintaining a physician-patient relationship conducive to identification and resolution of both organic and psychologic illness. Periodic medical re-evaluation approximately every 3 mo is warranted for early detection of other identifiable causes of chronic fatigue, especially with interval development of new symptoms.

Prognosis.

Chronic fatigue syndrome can persist for years with significant morbidity but no mortality. There are no increased risks of cancer, autoimmune disease, multiple sclerosis, opportunistic infections, or other complications.

The clinical course of chronic fatigue syndrome is highly variable. Patients should be instructed that their symptoms will likely wax and wane. Most adult patients never fully return to their pre-illness level of activity, but about 20% of patients return to their previous state of health for periods of at least 1 yr without any specific medical intervention. Some of these patients, however, subsequently have relapses. Approximately 60% of adult patients report gradual but marked improvement in symptoms over a period of 2–3 yr without specific therapy, although some patients appear to have no improvement or occasionally deteriorate. Patients who deal with stress by somatization and who deny the modulating role of psychosocial factors have a less favorable prognosis. The eventual clinical course is unpredictable, and many adult patients remain functionally impaired for years. Children and adolescents with chronic fatigue appear to have a more optimistic outcome, typically with an undulating course of gradual but substantial symptomatic improvement, or full recovery, 1–4 yr after diagnosis, and an overall good functional outcome in 80% of cases. Poor prognostic factors include increasing time missed from school, lower socioeconomic status, chronic maternal health problems, and untreated co-morbid psychiatric disorder.

Part 13 - The Immunologic System and Disorders

Section 1 - *Evaluation of the Immune System*

Rebecca H. Buckley

Chapter 112 - Evaluation of Suspected Immunodeficiency

Children with recurrent infections are among the most frequent types of patients seen by primary care physicians. The number of pediatric patients suspected of having primary or secondary immunodeficiency far exceeds the actual number of cases despite the emergence of the human immunodeficiency virus (HIV) epidemic. Most patients with recurrent infections do not have an identifiable immunodeficiency disorder. A major reason for the apparent high rate of recurrent infections is excessive exposure of infants or children to infectious agents in out-of-home child care and other group settings. In addition, excessive use of antibiotics by physicians has masked the classic presentation of many of the primary immunodeficiency diseases.

Primary care physicians must have a high index of suspicion if defects of the immune system are to be diagnosed early enough that appropriate treatment can be instituted before there is irreversible damage. This problem is made more difficult because none of these defects are screened for currently in the perinatal period or later in childhood, and there is widespread use of antibiotics for respiratory infections, which can mask genetic defects in the immune system. Evaluation of immune function should be initiated for children with clinical manifestations of a specific immune disorder or with unusual, chronic, or recurrent infections such as (1) two or more systemic or serious bacterial infections (e.g., sepsis, osteomyelitis, or meningitis); (2) three or more serious respiratory or documented bacterial soft tissue infections (e.g., cellulitis, draining otitis media, or lymphadenitis) within 1 yr; (3)

infections occurring at unusual sites (e.g., liver or brain abscess); (4) infections with unusual pathogens (e.g., *Aspergillus, Serratia marcescens, Nocardia,* or *Burkholderia cepacia*); and (5) infections with common childhood pathogens but of unusual severity.

The screening tests selected for immunologic evaluation should be broadly informative, reliable, and cost effective. Familiarity with certain clinical guidelines aids in the initial selection of tests. Patients with deficiencies of antibodies, phagocytic cells, or complement have recurrent infections with encapsulated bacteria. Thus, patients with only repeated viral infections (with the exception of persistent enterovirus infections) are not as likely to have any of these disorders. Children with defects in antibody production, phagocytic cells, or complement proteins may grow and develop normally despite their recurrent infections unless they develop bronchiectasis from repeated lower respiratory tract bacterial infections or have persistent enteroviral infections of the central nervous system. By contrast, patients with deficiencies in T-cell function usually develop opportunistic infections early in life and fail to thrive.

The initial evaluation of immunocompetence includes a thorough history, physical examination, and family history. Most immunologic defects can be excluded at minimal cost with the proper choice of screening tests (Table 112–1). A complete blood count (CBC), manual differential count, and erythrocyte sedimentation rate (ESR) are among the most cost-effective screening tests. If the ESR is normal, chronic bacterial or fungal infection is unlikely. If an infant's neutrophil count is persistently elevated in the absence of any signs of infection, a leukocyte adhesion deficiency should be suspected. If the absolute neutrophil count is normal, congenital and acquired neutropenia and leukocyte adhesion defects are excluded. If the absolute lymphocyte count is normal, the patient is not likely to have a severe T-cell defect. Normal lymphocyte counts are higher in infancy and early childhood than later in life. For example, at 9 mo of age—an age when infants affected with severe T-cell immunodeficiency are likely to present—the lower limit of normal is 4,500 lymphocytes/mm^3 (Chapter 710). Examination of red cells for Howell-Jolly bodies helps exclude congenital asplenia. If the platelet count is normal or platelet size is normal, Wiskott-Aldrich syndrome is excluded. If a CBC and a manual differential were performed on the cord blood of all infants, severe combined immunodeficiency (SCID) could be detected at birth, and lifesaving immunologic reconstitution could then be given to all such infants.

TABLE 112-1 -- **Initial Immunologic Testing of the Child with Recurrent Infections**

Complete Blood Count, Manual Differential, and Erythrocyte Sedimentation Rate
Absolute lymphocyte count (normal result [Chapter 710] makes T-cell defect unlikely)
Absolute neutrophil count (normal result [Chapter 710] precludes congenital or acquired neutropenia and (usually) both forms of leukocyte adhesion deficiency, in which elevated counts are present even between infections)
Platelet count (normal result excludes Wiskott-Aldrich syndrome)
Howell-Jolly bodies (presence suggests asplenia)
Erythrocyte sedimentation rate (normal result indicates chronic bacterial or fungal infection unlikely)
Screening Tests for B-Cell Defects
IgA measurement; if abnormal, IgG and IgM measurement
Isohemagglutinins
Antibody titers to tetanus, diphtheria, *H. influenzae*, and *S. pneumoniae*
Screening Tests for T-Cell Defects
Absolute lymphocyte count (normal result indicates T-cell defect unlikely)
Candida albicans intradermal skin test: 0.1?mL of a 1:1,000 dilution for patients older than 6 yr, 0.1?mL of a 1:100 dilution for patients younger than 6 yr
Screening Tests for Phagocytic Cell Defects
Absolute neutrophil count
Respiratory burst assay
Screening Test for Complement Deficiency
CH_{50}

Patients with abnormalities on any screening tests should be characterized as fully as possible before any type of immunologic treatment is begun unless there is a life-threatening illness. Some “abnormalities” may prove to be laboratory artifacts, and conversely, what may appear to be a straightforward diagnosis may prove to be a much more complex disorder. If results of the initial screening including the CBC and manual differential, immunoglobulin levels, and complement levels are normal,

evaluations of T-cell and phagocytic cell functions may be indicated for patients with recurrent or unusual bacterial infections.

B Cells.

The presence and titer of antibodies to type A and B red blood cell polysaccharide antigens (isohemagglutinins) is used as a simple screening test. As assayed in most blood banks, this test measures predominantly IgM antibodies. However, isohemagglutinins may be normally absent in the first 2 yr of life and are always absent if the patient is blood type AB. Because most infants and children have received diphtheria-tetanus-pertussis (DTaP), *Haemophilus influenzae* type b (Hib), and conjugate pneumococcal immunizations, it is informative to test for antibodies to diphtheria, tetanus, *H. influenzae* polyribose phosphate, and pneumococcal antigens. If the titers are low, measurement of antibodies to diphtheria or tetanus toxoids before and 2 wk after a pediatric DT booster is helpful in assessing the capacity to form IgG antibodies to protein antigens. To evaluate a patient's ability to respond to polysaccharide antigens, pneumococcal antibodies can be measured before and 3 wk after immunization with the polysaccharide pneumococcal vaccine in patients older than 2 yr. Antibodies detected in these tests are of the IgG isotype. These antibody studies can be performed in many laboratories but it is important to choose a reliable laboratory and to use the same laboratory to test before and after the booster.

Patients with significant or permanent B-cell defects do not produce either IgM or IgG antibodies normally. However, the finding of normal IgM and IgG antibody levels does not preclude IgA deficiency, transient hypogammaglobulinemia of infancy, or protein-losing states. Selective IgA deficiency, the most common B-cell defect, can be excluded by measuring serum IgA. If the IgA concentration is normal, most of the permanent types of hypogammaglobulinemia are also excluded, inasmuch as IgA is usually very low or absent in those conditions as well. If IgA is low, IgG and IgM should also be measured. Patients who are receiving corticosteroids or who have protein-losing states (e.g., nephrosis, protein-losing enteropathy) often have low IgG concentrations but make antibodies normally. Very high serum concentrations of one or more immunoglobulin classes suggest HIV infection or chronic granulomatous disease.

IgG subclass measurements are seldom helpful in assessing immune function in children with recurrent infections. It is difficult to discern the biologic significance of the various mild to moderate deficiencies of IgG subclasses, particularly when completely asymptomatic individuals have been described as totally lacking IgG1, IgG2, IgG4, and/or IgA1 owing to immunoglobulin heavy chain gene deletions. Moreover, a number of healthy children have been described as having low levels of IgG2 but normal responses to polysaccharide antigens when immunized. When children with low IgG2 subclass levels and histories of frequent infections were studied in depth, they were found to have broader immunologic dysfunction, including poor responses to protein antigens as well, suggesting that their condition may have been in the process of developing into common variable immunodeficiency (CVID). Only when antibody deficiencies are detected despite normal levels of immunoglobulins are IgG subclass measurements occasionally helpful. Children who completely lack IgG2 are usually unable to make antibodies to polysaccharide antigens; however, this can be true even in those with normal IgG2 levels. Thus, antibody measurements are far more cost effective than IgG subclass determinations.

Patients found to be agammaglobulinemic should have their blood B cells enumerated by flow cytometry using dye-conjugated monoclonal antibodies to B cell–specific CD antigens, usually CD19 or CD20. Normally, approximately 10% of circulating lymphocytes are B cells. In X-linked agammaglobulinemia (XLA) such cells are missing, whereas in CVID, IgA deficiency, and hyper IgM syndromes, B cells are usually present. This distinction is important because children with hypogammaglobulinemia from XLA and CVID can have different clinical problems, and the two conditions have different inheritance patterns. Patients with XLA have a heightened susceptibility to persistent enteroviral infections, whereas those with CVID have more problems with autoimmune diseases and lymphoid hyperplasia. Specific molecular diagnostic tests for XLA (Chapter 114.1) are necessary in cases without a family history to aid genetic counseling. Molecular testing is also indicated in other defects.

If results of all antibody tests prove to be normal and the immunoglobulins remain low, studies should be performed to confirm that the immunoglobulins are not being lost through the urinary or gastrointestinal tracts, such as occurs in nephrotic syndrome, protein-losing enteropathies, or intestinal lymphangiectasia.

T Cells.

The *Candida* skin test is the most cost-effective test of T-cell function. Adults and children older than 6 yr should be tested intradermally with 0.1?mL of a 1:1,000 dilution of a known potent *Candida albicans* extract. If the test result is negative at 24, 48, and 72?hr, a 1:100 dilution should be tested. The latter concentration can be used in the initial testing of children under 6 yr. If the test result is positive, as defined by erythema and induration of greater than 10?mm at 48?hr and the reaction is greater than at 24?hr, virtually all primary T-cell defects are precluded, which obviates the need for more expensive in vitro tests, such as lymphocyte phenotyping or assessments of responses to mitogens.

T cells and T-cell subpopulations can be enumerated by flow cytometry using dye-conjugated monoclonal antibodies recognizing CD antigens present on T cells, such as CD2, CD3, CD4, and CD8. This is a particularly important test to perform on any infant who is lymphopenic, because SCID is a pediatric emergency that can be successfully treated by bone marrow transplantation in more than 95% of cases if diagnosed before untreatable infections develop. CD3 T cells usually constitute 70% of peripheral lymphocytes. Normally there are roughly twice as many CD4 (helper) T cells as there are CD8 (cytotoxic) T cells. Because there are examples of severe immunodeficiency in which phenotypically normal T cells are present, tests of T-cell function are far more informative and cost effective than enumeration of T-cell subpopulations by flow cytometry. T cells are normally stimulated through their T-cell receptors (TCRs) by antigen present in the groove of major histocompatibility complex (MHC) molecules; however, the TCR can also be stimulated directly with mitogens such as phytohemagglutinin (PHA), concanavalin A (Con A), or pokeweed mitogen (PWM). After a 3–5-day period of incubation with the mitogen, the proliferation of T cells is measured by the incorporation of radiolabeled thymidine into DNA. Other stimulants that can be used to assess T-cell function in the same type of assay include antigens (e.g., *Candida* or tetanus toxoid) and allogeneic cells. Additional assays of T-cell function include the measurement of cytokine production

by T lymphocytes stimulated with mitogens (see Box 113–1).

Phagocytic Cells.

Killing defects of phagocytic cells, which should be suspected if a patient has recurrent staphylococcal abscesses or gram-negative infections, can be evaluated by screening tests measuring the neutrophil respiratory burst after phorbol ester stimulation. The most reliable and useful test of this type is a flow cytometry assessment of the respiratory burst

using rhodamine dye; this test has replaced the previously used nitroblue tetrazolium (NBT) dye test, which had technical problems with reproducibility. Leukocyte adhesion deficiencies can be easily diagnosed by flow cytometry assays of blood lymphocytes or neutrophils, using monoclonal antibodies to CD18 or CD11 (LAD1) or to CD15 (LAD2).

Natural killer (NK) cells can be enumerated by flow cytometry using monoclonal antibodies to NK-specific CD antigens, usually CD16 or CD56. NK function is assessed by a radiolabeled chromium-release assay using the K562 human erythroleukemia cell line as target cells, which are readily killed by NK cells.

Phagocytic cell defects can be further defined according to their molecular cause. Mutations in the genes encoding four different components of the electron transport chain have been discovered in various patients with chronic granulomatous disease (CGD). It is important to identify which molecular type of CGD is present as a basis for genetic counseling (one type is X linked, and the other three types are autosomal recessive), prenatal diagnosis, and the eventual prospect of gene therapy. In the case of the leukocyte adhesion deficiencies, early diagnosis is of crucial importance because bone marrow transplantation can be lifesaving. A confirmatory test for LAD1 (if flow cytometry suggests that defect) is NK cell function, because the lack of adhesion molecules prevents the NK cells of such patients from attaching to the target cells.

Complement.

The most effective screening test for complement defects is the CH_{50} assay, a bioassay that measures the intactness of the entire complement pathway and yields abnormal results if complement has been consumed from the specimen for any reason. Genetic deficiencies in the complement system are usually characterized by extremely low CH_{50} values. However, the most common cause of an abnormal CH_{50} result is a delay in or improper transport of the specimen to the laboratory. Specific immunoassays for C3 and C4 are commercially available, but further identification of other complement component deficiencies is usually possible only in research laboratories. Nevertheless, it is extremely important to identify which component is missing, because there are different disease susceptibilities depending on whether there are deficiencies of early or late components. Identifying the mode of inheritance is also important for genetic counseling. Properdin deficiency is X linked, but all of the other complement deficiencies are autosomal. Measurement of C4 can be helpful in assessing suspected hereditary angioedema.

Rebecca H. Buckley

Chapter 113 - T Lymphocytes, B Lymphocytes, and Natural Killer Cells

Bodily defense against infectious agents is secured through a combination of physical barriers, including the skin, mucous membranes, mucous blanket, and ciliated epithelial cells, and the various components of the immune system. The immune system consists of T lymphocytes, B lymphocytes, natural killer (NK) cells, dendritic and phagocytic cells, and complement proteins. The immune system also serves to protect against autoimmune diseases and malignancy.

LYMPHOPOIESIS IN THE FETUS

Origin of the Lymphoid System.

The human immune system arises in the embryo from gut-associated tissue. Pluripotential hematopoietic stem cells first appear in the yolk sac at 2.5–3 wk of gestational age and migrate to the fetal liver at 5 wk of gestation; they later reside in the bone marrow, where they remain throughout life (Fig. 113–1). Lymphoid stem cells develop from such precursor cells and differentiate into T, B, or NK cells, depending on the organs or tissues to which the stem cells traffic. Primary lymphoid organ (thymus and bone marrow) development begins during the middle of the first trimester of gestation and proceeds rapidly; secondary lymphoid organ (spleen, lymph nodes, tonsils, Peyer patches, and lamina propria) development soon follows. These organs continue to serve as sites of differentiation of T, B, and NK lymphocytes from stem cells throughout life. Both the initial organogenesis and the continued cell differentiation occur as a consequence of the interaction of a vast array of lymphocytic and microenvironmental cell surface molecules and proteins secreted by the involved cells. The complexity and number of such cell surface molecules led to the development of an international nomenclature and classification of these differentiation antigens, which are now referred to as **clusters of differentiation (CD)** (Table 113–1).

T and B lymphocytes are the only components of the immune system that have antigen-specific recognition capabilities; they are responsible for adaptive immunity. NK cells are lymphocytes that are also derived from hematopoietic stem cells and are thought to have a role in host defense against viral infections, tumor surveillance, and immune regulation. The proteins synthesized and secreted by T, B, and NK cells, and by the cells with which they interact, are referred to as **cytokines.** Several such

TABLE 113-1 -- CD Classification of Some Lymphocyte Surface Molecules

CD Number	Other Names	Tissue/Lineage	Function
CD1	T6	Cortical thymocytes; Langerhans cells	Antigen presentation to TCR?d cells
CD2	SRBC receptor	T and NK cells	Binds LFA-3 (CD58); alternative pathway of T cell activation
CD3	T3, Leu 4	T cells	TCR-associated; transduces signals from TCR
CD4	T4, Leu3a	Helper T cell subset	Receptor for HLA class II antigens; associated with p56 *lck* tyrosine kinase
CD7	3A1, Leu 9	T and NK cells and their precursors	Co-mitogenic for T lymphocytes
CD8	T8, Leu2a	Cytotoxic T cell subset; also on 30% of NK cells	Receptor for HLA class I antigens; associated with p56 *lck* tyrosine kinase
CD10	cALLA	B cell progenitors	Peptide cleavage
CD11a	LFA-1a a chain	T, B, and NK cells	With CD 18, ligand for ICAMS 1, 2, and 3
CD11b,c	MAC-1,CR3; CR4	NK cells	With CD18, receptors for C3bi
CD16	FcR?III	NK cells	FcR for IgG
CD19	B4	B cells	Regulates B cell activation
CD20	B1	B cells	Mediates B cell activation
CD21	B2	B cells	C3d and the EBV receptor; CR2
CD34	My10	Precursor cells	Unknown

CD40	CD40	B cells and monocytes	Initiates isotype switching when ligated
CD45	Leukocyte common antigen, T200	All leukocytes	Tyrosine phosphatase that regulates lymphocyte activation; CD45R0 isoform on memory T cells, CD45RA isoform on naive T cells
CD56	N-CAM; NKH-1	NK cells	Mediates NK homotypic adhesion
CD154	CD40 ligand, gp39	Activated CD4 T cells	Ligates CD40 on B cells and initiates isotype switching

CD = clusters of differentiation.

proteins have been given an official nomenclature as **interleukins (ILs)** (Box 113–1). Cytokines have the ability to act in an autocrine, paracrine, or endocrine manner to promote and facilitate differentiation and proliferation of the cells of the immune system.

T-Cell Development and Differentiation.

The primitive thymic rudiment is formed from the ectoderm of the third branchial cleft and endoderm of the third branchial pouch at 4 wk gestation. Beginning at 7–8 wk, the right and left rudiments move caudally and fuse in the midline. Blood-borne T-cell precursors from the fetal liver then begin to colonize the perithymic mesenchyme at 8 wk gestation. These precursor **pro-T cells** are identified by surface proteins designated as CD7 and CD34. At 8–8.5 wk gestation, CD7 cells are found intrathymically, and some cells also co-express CD4, a protein present on the surfaces of mature T-helper (TH) cells, and CD8, a protein found on both mature cytotoxic cells and NK cells. In addition, some cells bear single T-cell receptor (TCR, Ti) chains (s, d, or ?) but none bear complete TCRs.

The mature TCR is a heterodimer of two chains, either a and s or ? and d; it is co-expressed on the cell surface with CD3, a complex of five polypeptide chains (?, d, e, ?, ?). TCR gene rearrangement occurs by a process in which large, noncontiguous blocks of DNA are spliced together. These segments, known as **V (variable), D (diversity)**, and **J (joining)**, each have a number of variants. VDJ segments are joined to a constant region of the a gene, and VJ segments are joined to the s gene to complete the receptor polypeptide genes. Random combinations of the segments account for much of the enormous diversity of TCRs that enables humans to recognize millions of different antigens. TCR gene rearrangement requires the presence of **recombinase activating genes**, referred to as RAG-1 and RAG-2, as well as other recombinase components. This process is flawed in mice with severe combined immunodeficiency (SCID) and in some humans with SCID. Rearrangement of TCR genes signifies commitment of pro-T cells to T-lineage development—that is, to become pre-T cells. TCR gene rearrangement begins shortly after colonization of the thymus with stem cells, and the establishment of the T-cell repertoire begins at 8–10 wk of gestation. By 9.5–10 wk, more than 95% of thymocytes express CD7, CD2, CD4, CD8, and c(cytoplasmic) CD3, and approximately 30% bear the CD1 inner cortical thymocyte antigen. By 10 wk, 25%

Box 113-1. Functional Classification of Cytokines*

CYTOKINES INVOLVED IN NATURAL IMMUNE RESPONSES

Type I interferons–IFN-a and IFN-ß–inhibit viral replication, inhibit cell proliferation, activate NK cells, upregulate class I MHC molecule expression

TNF-a–mediates host response to gram-negative bacteria and other infectious agents

IL1a and -ß–mediate host inflammatory response to infectious agents

IL1Ra–is a natural antagonist of IL1, blocks signals delivered by IL1

IL6–mediates and regulates inflammatory responses

Chemokines (IL8, monocyte chemotactic protein-1 or MCP-1, RANTES, and others)–mediate leukocyte chemotaxis and activation

LYMPHOCYTE REGULATORY CYTOKINES

Immunostimulatory or Growth-Promoting

IL1–co-stimulates activation of T cells

IL2–growth factor for T, B, NK cells; activates effector cells

IL4–T and B cell growth factor; stimulates IgE production; upregulates class I and II MHC molecule and FcRell expression on macrophages; expansion of T_H 2 subset

IL5–B cell growth and activation

IL6–growth factor for B cells

IL7–stromal cell factor; growth factor for precursor B and T cells, T cell homeostatic factor

IL10–growth and differentiation factor for B cells

IL9–growth factor for T cells, B cells, mast cells, eosinophils, neutrophils,

IL7–stromal cell factor; growth factor for precursor B and T cells, T cell homeostatic factor

IL10–growth and differentiation factor for B cells

IL9–growth factor for T cells, B cells, mast cells, eosinophils, neutrophils, endothelial cells

IL12–expansion of T_H 1 subset; activates effector cells

IL13–growth and differentiating factor for B cells; stimulates IgE production; upregulates class I and II MHC molecule and FcRell expression on macrophages

TNF-ß–stimulates effector cell function

IL15–growth factor for NK cells

IL18–induces IFN-?, GM-CSF, TNF-a in immunocompetent cells

IFN-?–activates macrophages, NK cells; upregulates class I and II MHC molecule expression; inhibits IL4-or IL13-induced IgE production

Immunosuppressive

IL1Ra–regulates IL1 activities

TGF-ß–antagonizes lymphocyte responses

IL10–inhibits activities of T_H 1 cells

IFNa/ß–inhibits production of IFN?

HEMATOPOIESIS REGULATING CYTOKINES

GM-CSF, G-CSF, M-CSF–colony stimulating factors

Erythropoietin (EPO)–differentiation of erythroid precursors

IL3, SCF, *c-kit* receptor–regulate stem cell development

IL4–mast cell development

IL5–eosinophil differentiation and proliferation

IL6–differentiation of B cells

IL7–differentiation of B and T cells

IL8–promotes cell survival in response to hematopoietic cytokines

IL11–elevates platelet count in patients given chemotherapy

IL12–expands and activates resting NK cells

IL8–promotes cell survival in response to hematopoietic cytokines

IL11–elevates platelet count in patients given chemotherapy

IL12–expands and activates resting NK cells

IL15–expands and activates resting NK cells

IL21–limits viability of NK cells

PRO-INFLAMMATORY CYTOKINES

IL1, TNF-a, IL6–participate in the acute-phase response and synergize to mediate inflammation, shock, and death

IL12–stimulates INF? production by T and NK cells

IL17–recruitment and activation of airway neutrophils via chemokines

IL18–induces IFN?, GM-CSF, TNFa and upregulates chemokine receptors

ANTI-INFLAMMATORY CYTOKINES

IL4–reduces endotoxin-induced TNF and IL1 production

IL6–inhibits TNF production

IL10–suppresses lymphocyte functions and downregulates production of pro-inflammatory cytokines; anti-atherogenic

IL11–cytoprotective effect on bowel mucosa, skin, and joint inflammation

IL13–downregulates functions of macrophages, suppresses production of proinflammatory cytokines

TGF-ß–has immunosuppressive effects, inhibits IL1 and TNF gene expression

IL1Ra–competes with the binding of IL1 to its cell surface receptors and blocks IL1R

TNFsR–soluble TNF receptors, by binding TNF, block interaction of TNF with the target cell

IL = interleukin; MHC = major histocompatibility complex; NK = natural killer; SCF = stem cell factor; TNF = tumor necrosis factor.

Modified from Whiteside TL: Cytokine measurements and interpretation of cytokine assays in human disease. J Clin Immunol 1994;14:327–9.

*This is not an exhaustive list.

of thymocytes bear aß TCRs. Ti aß T cells gradually increase in number during embryonic life and represent more than 95% of thymocytes postnatally.

As immature cortical thymocytes begin to express TCRs, the processes of positive and negative selection take place. **Positive selection** occurs through the interaction of immature thymocytes (which express low levels of TCR) with major histocompatibility complex (MHC) antigens present on cortical thymic epithelial cells. As a result, thymocytes with TCR capable of interacting with foreign antigens presented on self MHC antigens are activated and develop to maturity. Mature thymocytes that survive the selection process either express CD4 and are restricted to self class II HLA antigens or express CD8 and are restricted to self class I HLA antigens when they interact with foreign antigens presented by these MHC molecules. **Negative selection** occurs next and is mediated by interaction of the surviving thymocytes, which have much higher levels of TCR expression, with host peptides presented by HLA class I or II antigens present on bone marrow–derived thymic macrophages, dendritic cells, and possibly B cells. This interaction mediates programmed cell death of such autoreactive thymocytes by a process called **apoptosis**. Fetal cortical thymocytes are among the most rapidly dividing cells in the body; they increase in number by 100,000-fold within 2 wk after stem cells enter the thymus. As these cells mature, the previously mentioned selection process takes place, and as a consequence, 97% of all cortical thymocytes die. The surviving cells are no longer doubly positive for both CD4 and CD8 but are singly positive for either one or the other, and they migrate to the medulla.

T-cell functions are acquired concomitantly with the development of single-positive thymocytes, but they are not fully developed until the cells emigrate from the thymus. It has been estimated that one stem cell gives rise to approximately 3,000 mature medullary thymocytes. Such medullary cells are resistant to the lytic effects of corticosteroids. T cells begin to emigrate from the thymus to the spleen, lymph nodes, and appendix at 11–12 wk of embryonic life and to the tonsils by 14–15 wk. They leave the thymus via the bloodstream and are distributed throughout the body, with heaviest concentrations in the paracortical areas of lymph nodes, the periarteriolar areas of the spleen, and the thoracic duct lymph. Recent thymic emigrants co-express the CD45RA isoforms and CD62L (L-selectin). Rearrangement of the TCR locus during this process leads to the formation of circular episomes as a by-product. These signal joint TCR recombination excision circles (TRECs) can be detected in T cells that are recent thymic emigrants, whereas T cells that develop extrathymically do not contain these episomes. The homing of lymphocytes to peripheral lymphoid organs is directed by the interaction of a lymphocyte surface adhesion molecule, L-selectin, with carbohydrate moieties on

specialized regions of lymphoid organ blood vessels, called high endothelial venules. By 12 wk gestation, T cells can proliferate in response to plant lectins, such as phytohemagglutinin (PHA) and concanavalin A (Con A), and to allogeneic cells; antigen-binding T cells have been found by 20 wk gestation. Hassall corpuscles (bodies), which are swirls of terminally differentiated medullary epithelial cells, are first seen in the thymic medulla at 16–18 wk of embryonic life.

B-Cell Development and Differentiation.

In parallel with T-cell differentiation, B-cell development begins in the fetal liver before 7 wk gestation. Fetal liver CD34 stem cells are seeded to the bone marrow of the clavicles by 8 wk of embryonic life and to that of the long bones by 10 wk (see Fig. 113–1). **Antigen-independent** stages of B-cell development have been defined according to immunoglobulin gene rearrangement patterns and the surface proteins the cells bear. The **pro–B cell** is the first descendent of the pluripotential stem cell committed to B-lineage development and is detected by the presence of both CD34 and CD10 on its surface; in it the immunoglobulin genes remain germ line (Fig. 113–2). The next stage is the **pre-pre–B cell** stage, during which immunoglobulin genes are rearranged, but there is no cytoplasmic expression of μ heavy chains or surface IgM (sIgM); these cells are further characterized by the co-expression of membrane CD34, CD10, CD19, and CD40, and somewhat later by the additional presence of CD73, CD22, CD24, and CD38. The **pre–B cell** stage is next; these cells are distinguished by the expression of cytoplasmic μ heavy chains but no sIgM, because no immunoglobulin light chains are produced yet. They also continue to express all CD antigens seen at the pre-pre–B cell stage except CD34 and CD10 (which are lost); in addition, they express CD21. Next is the **immature B-cell** stage, during which sIgM is expressed, because light-chain genes have now been rearranged, but not sIgD; CD38 is lost, but all other pre–B-cell CD antigens persist. The last stage of antigen-independent B-cell development is the **mature or virgin B cell**, which co-expresses both sIgM and sIgD; CD23 is also acquired at this stage, and all of the other CD antigens present on immature B cells persist. Pre-B cells can be found in fetal liver at 7 wk gestation, sIgM+ and sIgG+ B cells at between 7 and 11 wk, and sIgD+ and sIgA+ B

Figure 113-2 Antigen-independent human B-cell development. (From Haynes BF, Denning SM: Lymphopoiesis. In Stamatoyannopoulis G, Nienhuis A, Majerus P, Varmus H [editors]: *Molecular Basis of Blood Diseases*, 2nd ed. Philadelphia, WB Saunders, 1994.)

cells by 12–13 wk. By 14 wk of embryonic life, the percentage of circulating lymphocytes bearing sIgM and sIgD is the same as in cord blood and slightly higher than in the blood of adults.

Antigen-dependent stages of B-cell development are those that develop after the mature or virgin B cell is stimulated by antigen through its antigen receptor (sIg); the outcome is the differentiation of the cell and its progeny into sIg+ memory (CD27) B cells (for that particular antigen) and plasma cells, which synthesize and secrete antigen-specific immunoglobulin—that is, antibody. Deficiency of activation-induced cytidine deaminase (AID), as seen in one form of autosomal recessive hyper IgM, can result in a failure of isotype switching so that only IgM antibodies are formed. There are five **immunoglobulin isotypes**, which are defined by unique heavy-chain antigens present on each: IgM, IgG, IgA, IgD, and IgE. IgG and IgM, the only complement-fixing isotypes, are the most important immunoglobulins in the blood and other internal body fluids for protection against infectious agents; IgM is confined primarily to the intravascular compartment because of its large size, whereas IgG is present in all internal body fluids. IgA is the major protective immunoglobulin of external secretions—that is, those of the gastrointestinal, respiratory, and urogenital

tracts—but it is also present in the circulation. IgE, present in both internal and external body fluids, has a major role in host defense against parasites. However, because of high-affinity IgE receptors on basophils and mast cells, IgE is the principal mediator of allergic reactions of the immediate type. The significance of IgD is still not clear. There are also immunoglobulin subclasses (again defined by unique heavy-chain antigens present on each, in addition to their class-specific heavy-chain antigen), including four subclasses of IgG—IgG1, IgG2, IgG3, and IgG4—and two subclasses of IgA—IgA1 and IgA2. These subclasses each have different biologic roles; for example, antipolysaccharide antibody activity is found predominantly in the IgG2 subclass. Secreted IgM and IgE have been found in abortuses as young as 10 wk, and IgG as early as 11–12 wk. Even though these B-cell developmental stages have been described in the context of B-cell ontogeny, it is important to recognize that the process of B-cell development from pluripotential stem cells goes on throughout postnatal life.

Despite the capacity of fetal B lymphocytes to differentiate into immunoglobulin-synthesizing and -secreting cells, plasma cells are not usually found in lymphoid tissues of a fetus until about 20 wk gestation, then only rarely, because of the sterile environment of the uterus. Peyer patches have been found in significant numbers by the 5th intrauterine month, and plasma cells have been seen in the lamina propria by 25 wk gestation. Before birth there may be primary follicles in lymph nodes, but secondary follicles are usually not present.

A human fetus begins to receive significant quantities of maternal IgG transplacentally at around 12 wk gestation, and the quantity steadily increases until at birth cord serum contains a concentration of IgG comparable to or greater than that of maternal serum. IgG is the only class to cross the placenta to any significant degree; all four subclasses do this, but IgG2 does so least well. A small amount of IgM (10% of adult levels) and a few nanograms of IgA, IgD, and IgE are normally found in cord serum; because none of these proteins crosses the placenta, they are presumed to be of fetal origin. These observations raise the possibility that certain antigenic stimuli normally cross the placenta to provoke responses, even in uninfected fetuses. Some atopic infants occasionally have reaginic antibodies to antigens, such as egg white, to which they have had no known exposure during postnatal life, suggesting that synthesis of these IgE antibodies could have been induced in the fetus by antigens ingested by the mother.

Natural Killer (NK)–Cell Development.

NK-cell activity has been found in human fetal liver cells at 8–11 wk of gestation. NK lymphocytes are also derived from bone marrow precursors. Thymic processing is not necessary for NK-cell development, although NK cells have been found in the thymus. They are defined by their functional capacity to mediate non–MHC-restricted (classic) cytotoxicity. NK cells also have killer inhibitory receptors (KIRS) that recognize certain MHC antigens and inhibit the killing of normal allogeneic cells in four specific patterns of reactivity. The genetic locus controlling these patterns is different from conventional MHC alloantigenic loci, although it has been mapped to chromosome 6 in the region of the MHC class I genes. Unlike T and B cells, NK cells do not rearrange antigen receptor genes during their development. Virtually all NK cells express CD56, and more than 90% bear CD16 (Fc? RIII) molecules on their cell surface. Other CD antigens found on NK cells include CD57 (on 50–60%), CD7 and CD2 (70–90%), and CD8 (30–40%) (see Table 113–1). Because NK cells share surface antigens with T and myeloid cells, the lineage relationship of NK cells to the latter is still unclear. Some humans with SCID and profound deficiencies in T and B cells have abundant NK cells, whereas some humans who have no NK cells may have normal T- and B-cell development. After release from bone marrow, NK cells enter the circulation or migrate to the spleen; there are very few NK cells in lymph nodes. In normal individuals, NK cells represent 10% of lymphocytes; this percentage is often slightly lower in cord blood.

Immune Cell Interactions.

Immune cell interaction is of crucial importance to all phases of the adaptive immune response. Unlike the B-cell antigen receptor (Ig), which can recognize native antigen, the TCR can recognize only processed antigenic peptides presented to it by MHC molecules such as **HLA-A,-B, and -C antigens (class I antigens)** and **HLA-DR, -DP, and -DQ (class II antigens)** molecules present on **antigen-presenting cells (APCs)**. The MHC molecules have a groove in their protein structure where peptides fit. Class I MHC molecules are found on most nucleated cells in the body. Class II MHC molecules are found on macrophages, dendritic cells, and B cells. The peptides found in the groove of class I HLA molecules come from proteins normally made in the cell that are degraded and inserted into the groove. The peptides include viral peptides if the cell is infected with a virus. The peptides present in the groove of class II molecules come from exogenous native antigens such as vaccine and bacterial proteins. These proteins are taken up by APCs (macrophages, dendritic cells, and B cells), degraded, and expressed on the cell surface in the groove of class II HLA molecules. The TCR then interacts with the peptide-bearing HLA molecule and, through its functional and physical link to the CD3 complex of signal-transducing molecules, sends a signal to the T cell to produce cytokines that ultimately result in T-cell activation and proliferation.

Two of the main functions of T cells are (1) to signal B cells to make antibody by producing cytokines and membrane molecules that can serve as ligands for B-cell surface molecules and (2) to kill virally infected cells or tumor cells. For a T cell to carry out either of these functions, it first must bind to an APC or to a target cell. For high-affinity binding of T cells to APCs or target cells, several molecules on T cells, in addition to TCRs, bind to molecules on APCs or target cells. For example, the CD4 molecule present on TH cells binds directly to MHC class II molecules on APCs. CD8 on killer T cells binds the MHC class I molecule on the target cell. Both CD4 and CD8 molecules are directly involved in the regulation of T-cell activation and are physically linked intracellularly to the p56-lck protein tyrosine kinase. The cytoplasmic tail of CD45 is a tyrosine phosphatase capable of regulating T-cell signal-transduction events by virtue of the fact that p56-lck has been shown to be a substrate for CD45 phosphatase activity. Depending on which isoform of CD45 is present on the T cell (CD45RO on memory T cells, CD45RA on naive T cells), mechanisms by which CD45 could upregulate or downregulate T-cell triggering have been proposed. LFA-1 on the T cell binds a protein called ICAM-1 (intracellular adhesion molecule 1), now designated CD54, on APCs. CD2 on T cells binds LFA-3 (CD58) on the APCs. With the adhesion of T cells to antigen-presenting cells, TH cells are stimulated to make interleukins and upregulate cell surface molecules, such

as the CD40 ligand (CD154), that provide help for B cells, and cytotoxic T cells are stimulated to kill their targets.

In the **primary antibody response**, native antigen is carried to a lymph node draining the site, taken up by specialized cells called follicular dendritic cells (FDCs), and expressed on their surfaces. Virgin B cells bearing sIg specific for that antigen then bind to the antigen on the surfaces of the FDCs. If the affinity of the B-cell sIg antibody for the antigen present on the FDCs is high enough, and if other signals are provided by activated T-helper cells, the B cell develops into an antibody-producing plasma cell. If the affinity is not high enough or if T-cell signals are not received, the B cell dies through apoptosis. The signals provided by activated TH cells include those from cytokines they secrete (IL-4, IL-5, IL-6, and IL-13; see Box 113–1) and that from a surface T-cell molecule, CD154, which, on contact of the T cell with the B cell, binds to CD40 on the B-cell surface. CD40 is a type I integral membrane glycoprotein expressed on B cells, monocytes, some carcinomas, and a few other types of cells. It belongs to the tumor necrosis factor (TNF)/nerve growth factor receptor family. Cross linking of CD40 on B cells by allowing CD40 to interact with CD154 in the presence of certain cytokines causes the B cells to undergo proliferation and to initiate immunoglobulin synthesis. In the primary immune response, only IgM antibody is usually made, and most of it is of relatively low affinity. Some B cells become memory B cells during the primary immune response. These cells switch their immunoglobulin genes so that IgG, IgA, and/or IgE antibodies of higher affinity are formed on a secondary exposure to the same antigen. The secondary immune response occurs when these memory B cells again encounter that antigen. Plasma cells form, just as in the primary response; however, many more cells are rapidly generated, and IgG, IgA, and IgE antibodies are made. In addition, genetic changes in immunoglobulin genes (somatic mutation) lead to increased affinity of those antibodies. The exact pattern of isotype response to antigen varies, depending

---

on the type of antigen and the cytokines present in the microenvironment.

For NK-mediated lysis, binding to the target is of crucial importance. This is best exemplified by humans with mutations in CD18, or the ß chain of three different adhesion molecules, who also lack NK function. Thus, binding of NK cells to their targets is facilitated by LFA-1-ICAM interactions. CD56 or NCAM (neural cell adhesion molecule) also mediates homotypic adhesion of NK cells. Fc?RIII, or the low-affinity IgG receptor, has a higher affinity for IgG when it is present on NK cells than when it is on neutrophils; it permits NK cells also to mediate antibody-dependent cellular cytotoxicity (ADCC). In this reaction, antibody is bound through its Fc region to the Fc?RIII. The antibody-combining portion of the IgG attaches to the target. The NK cell, now attached to the target by antibody, kills the target cell.

POSTNATAL LYMPHOPOIESIS

T Cells and T-Cell Subsets.

Although the percentage of CD3 T cells in cord blood is somewhat less than in the peripheral blood of children and adults, T cells are actually present in higher number because of a higher absolute lymphocyte count in all normal infants. An additional distinction is that the ratio of CD4 to CD8 T cells is usually higher (3.5–4:1) in cord blood than in blood of children and adults (1.5–2:1). Virtually all T cells in cord blood bear the CD45RA (naive) isoform, and a dominance of CD45RA over CD45RO T cells persists during the first 2–3 yr of life, after which time the numbers of cells bearing these two isoforms gradually equalize. TH cells can be further subdivided according to the cytokines they produce when activated. **TH1 cells** produce IL-2 and IFN-?, which promote cytotoxic T-cell or delayed hypersensitivity types of responses, whereas **TH2 cells** produce IL-4, IL-5, IL-6, and IL-13 (see Box 113–1), which promote B-cell responses and allergic sensitization. Cord blood T cells have the capacity to respond normally to the two T-cell mitogens, PHA and Con A, and are capable of mounting a normal mixed leukocyte response. Normal newborn infants also have the capacity to develop antigen-specific T cell responses at birth, as evidenced by vigorous tuberculin reactivity a few weeks after BCG vaccination even on day 1 of life. Because patients in the first few months of life may have unrecognized severe T-cell defects, most hospitals now routinely irradiate all blood products given young infants.

B Cells and Immunoglobulins.

Newborn infants have increased susceptibility to infections with gram-negative organisms because they have not received IgM antibodies, which are **heat-stable opsonins**, to these organisms from the mother. The level of the **heat-labile opsonin**, C3b, is also lower in newborn serum than in adults. These factors probably account for impaired phagocytosis of some organisms by newborn polymorphonuclear cells. Maternally transmitted IgG antibodies serve quite adequately as heat-stable opsonins for most gram-positive bacteria, and IgG antibodies to viruses afford adequate protection against those agents. However, because there is a relative deficiency of the IgG2 subclass, antibodies to capsular polysaccharide antigens may be deficient. Because premature infants have received less maternal IgG by the time of birth than full-term infants, their serum opsonic activity is low for all types of organisms.

B lymphocytes are present in cord blood in slightly higher percentages but considerably higher numbers than in the blood of children and adults, reflecting the higher absolute lymphocyte counts in all normal infants. However, cord blood B cells do not synthesize the range of immunoglobulin isotypes made by B cells from children and adults when stimulated with pokeweed mitogen (PWM) or anti-CD40 plus IL-4 or IL-10, producing primarily IgM and at a much reduced quantity.

Neonates begin to synthesize antibodies of the IgM class at an increased rate very soon after birth in response to the immense antigenic stimulation of their new environment. Premature infants appear to be as capable of doing this as do full-term infants. At about 6 days after birth, the serum concentration of IgM rises sharply. This rise continues until adult levels are achieved by approximately 1 yr of age. Cord serum from noninfected normal newborns does not contain detectable IgA. Serum IgA is normally first detected at around the 13th day of postnatal life; the level gradually increases during early childhood until adult levels are achieved and

preserved between the 6th and 7th yr of life. Cord serum contains an IgG concentration comparable to or greater than that of maternal serum. Maternal IgG gradually disappears during the first 6–8 mo of life, while the rate of infant IgG synthesis increases (IgG1 and IgG3 faster than IgG2 and IgG4 during the 1st year) until adult concentrations of total IgG are reached and maintained by 7–8 yr of age. However, IgG1 and IgG4 reach adult levels first, followed by IgG3 at 10 yr and IgG2 at 12 yr of age. The total immunoglobulin level in infants usually reaches a low point at approximately 3–4 mo of postnatal life. The rate of development of IgE generally follows that of IgA. After adult concentrations of each of the three major immunoglobulins are reached, these levels remain remarkably constant for a normal individual. The capacity to produce specific antibodies to protein antigens is intact at the time of birth. However, normal infants cannot produce antibodies to polysaccharide antigens until usually after age 2 yr unless the polysaccharide is conjugated to a protein carrier, as is the case for the conjugate *Haemophilus influenzae* type b (Hib) and *Streptococcus pneumoniae* vaccines.

NK Cells.

The percentage of NK cells in cord blood is usually lower than in the blood of children and adults, but the absolute number of NK cells is approximately the same owing to the higher lymphocyte count. The capacity of cord blood NK cells to mediate target lysis in either NK-cell assays or ADCC assays is roughly two thirds that of adults.

Lymphoid Organ Development.

Lymphoid tissue is proportionally small but rather well developed at birth and matures rapidly in the postnatal period. The thymus is largest relative to body size during fetal life and at birth is ordinarily two thirds of its mature weight, which it attains during the 1st year of life. It reaches its peak mass, however, just before puberty, and then gradually involutes thereafter. By 1 yr of age, all lymphoid structures are mature histologically. Absolute lymphocyte counts in the peripheral blood also reach a peak during the 1st yr of life. Peripheral lymphoid tissue increases rapidly in mass during infancy and early childhood. It reaches adult size by approximately 6 yr of age, exceeds those dimensions during the prepubertal years, and then undergoes involution coincident with puberty. The spleen, however, gradually accrues its mass during maturation and does not reach full weight until adulthood. The mean number of Peyer patches at birth is one half the adult number, and gradually increases until the adult mean number is exceeded during adolescent years.

INHERITANCE OF ABNORMALITIES IN T-, B-, AND NK-CELL DEVELOPMENT

More than 100 immunodeficiency syndromes have been described. Until recently, there was little insight into the fundamental problems underlying most of these conditions. However, specific molecular defects have been identified in more than one third of these diseases. Most are recessive traits, several of which are caused by mutations in genes on the X chromosome and others by mutations on autosomal chromosomes. The molecular bases of six X-linked immunodeficiency disorders affecting T, B, and/or NK cells have been reported (Chapters 114–116): X-linked immunodeficiency with hyper IgM, X-linked lymphoproliferative syndrome, X-linked agammaglobulinemia, X-linked SCID, the Wiskott-Aldrich syndrome,

and nuclear factor kappa B essential modulator (NEMO). Examples of the autosomal defects include (1) combined immunodeficiencies due to abnormalities of purine salvage pathway enzymes, either adenosine deaminase (ADA, encoded by a gene on chromosome 20q13-ter) or purine nucleoside phosphorylase (PNP, encoded by a gene on chromosome 14q13.1); (2) mutations in the gene encoding ZAP-70 (localized to chromosome 2q12), a non-src family protein tyrosine kinase important in T-cell signaling; and (3) mutations in the gene encoding Janus kinase 3 (Jak3), the primary signal transducer from the common cytokine receptor ? chain (?c). The identification and cloning of the genes for these immunodeficiency diseases have obvious implications for potential future somatic cell gene therapy for these patients.

PRENATAL DIAGNOSIS AND CARRIER DETECTION

Intrauterine diagnosis of ADA and PNP deficiencies can be established by enzyme analyses on amnion cells (fresh or cultured) obtained before 20 wk gestation. Diagnosis of several X-linked defects can be made by direct mutation analysis of the X chromosome of cells obtained by chorionic villus sampling or by amniocentesis from male infants whose mothers have been identified as carriers. Diagnosis of enzyme-normal SCID or other severe T-cell deficiencies, MHC class I and/or II antigen deficiencies, chronic granulomatous disease (CGD), or Wiskott-Aldrich syndrome (by platelet size) can be established by appropriate tests of phenotype or function on small samples of blood obtained by fetoscopy at 18–22 wk of gestation, but this procedure carries significant risk. The same diagnostic procedures can be done on cord blood, but tragically no immunodeficiency disorders are screened for on the cord blood of infants born in the United States or elsewhere. Carriers of ADA and PNP deficiency can be detected by quantitative enzyme analyses of blood samples. Carriers of X-linked agammaglobulinemia, X-linked SCID, or the Wiskott-Aldrich syndrome can be identified by techniques designed to detect nonrandom X-chromosome inactivation in one or more blood cell lineages or by direct mutation analysis if the family's mutation is known.

Chapter 114 - Primary Defects of Antibody Production

Of all of the primary immunodeficiency diseases, those affecting antibody production are most frequent. Selective absence of serum and secretory IgA is the most common defect, with rates ranging from 1/333 persons to 1/16,000 among different races. By contrast, it has been estimated that agammaglobulinemia occurs with a frequency of only 1/50,000 persons. Patients with antibody deficiency are usually recognized because they have recurrent infections with encapsulated bacteria or a history of failure of responding to antibiotic treatment, but some individuals with selective IgA deficiency or infants with transient hypogammaglobulinemia may have few or no infections. The defective gene products for many primary antibody deficiency disorders have been identified (Table 114–1). Sometimes the defect is not in the B cell itself but in the T cells that are required for B cell function.

X-LINKED (XLA OR BRUTON) AGAMMAGLOBULINEMIA

Patients with X-linked agammaglobulinemia (XLA) have a profound defect in B lymphocyte development resulting in severe hypogammaglobulinemia, an absence of circulating B cells, small to absent tonsils, and no palpable lymph nodes.

Genetics and Pathogenesis.

The abnormal gene in XLA maps to q22 on the long arm of the X chromosome and encodes the B-cell protein tyrosine kinase ***Btk*** **(Bruton tyrosine kinase)**. *Btk* is a member of the *Tec* family of cytoplasmic protein tyrosine kinases that is expressed at high levels in all B-lineage cells, including pre–B cells. This kinase appears to be necessary for pre–B-cell expansion and maturation into surface Ig-expressing B cells, but probably has a role at all stages of B-cell development. It has not

TABLE 114-1 -- **Primary Antibody Deficiency Disorders**

Chromosome and Region	Gene Product	Disorder	Functional Deficiencies
2p11[*]	? chain	? chain deficiency	Absence of immunoglobulins bearing ? chains

6p21.3	Unknown	Selective IgA deficiency; CVID	Low or absent IgA; low concentrations of all immunoglobulins in CVID
12p13*	Activation-induced cytidine deaminase	Autosomal recessive hyper IgM	Failure to produce IgG, IgA, and IgE antibodies
14q32.3*	Immunoglobulin heavy chains	B cell-negative agammaglobulinemia (µ) or selective deficiencies of other isotypes	Absence of antibody production and lack of B cells in µ chain mutations; subclasses missing but B cells present in others
20*	CD40	Autosomal recessive hyper IgM	Failure to produce IgG, IgA, and IgE antibodies
Xq22*	Bruton tyrosine kinase	X-linked (Bruton) agammaglobulinemia (XLA)	Absence of antibody production, lack of B cells
Xq25*	SLAM-associated protein (SH2D1A)	X-linked lymphoproliferative disease (XLP)	Lack of anti-EBNA and long-lived T-cell immunity; low immunoglobulins
Xq26*	CD154 (CD40 ligand)	X-linked hyper IgM	Failure to produce IgG, IgA, and IgE antibodies
Xq28*	Nuclear factor ?B (NF-?B) essential modulator (NEMO)	Anhidrotic ectodermal dysplasia with immunodeficiency	Hyper IgM or IgG subclass and anti-polysaccharide antibodies

CVID = common variable immunodeficiency; EBNA = Epstein-Barr virus nuclear antigen; SLAM = signaling lymphocyte activation molecule.

Gene cloned and sequenced, gene product known.

been detected in any cells of T lineage, but it has been found in cells of the myeloid series. Thus far, all males with known XLA (by family history) have had low or undetectable *Btk* mRNA and kinase activity. Mutations in the *Btk* gene also occur in some agammaglobulinemic boys with no family history of XLA. To date more than 250 different mutations in the human *Btk* gene have been recognized and they encompass most parts of the coding portions of the gene. There is not a clear correlation between the location of the mutation and the clinical phenotype (Fig. 114–1). Carriers are detected by identifying nonrandom X-chromosome inactivation in B cells or by direct mutation analysis. Prenatal diagnosis of affected male fetuses is possible by mutation analysis, if the defect is known in the family.

The expression of *Btk* in cells of myeloid lineage is of interest because boys with XLA often have neutropenia at the height of an acute infection. It is conceivable that *Btk* is only one of the signaling molecules participating in myeloid maturation and that neutropenia is observed in XLA only when rapid production of such cells is needed. Some pre–B cells are found in the bone marrow; however, peripheral blood B lymphocytes are absent or present in very low numbers. In most patients, the percentage of T cells is increased, ratios of T-cell subsets are normal, and T-cell function is intact. The thymus was morphologically normal in patients who underwent autopsy.

Four autosomal recessive defects have also been shown to result in agammaglobulinemia with an absence of circulating B cells, including mutations in the genes encoding (1) the *µ* heavy chain gene; (2) the Igα signaling molecule; (3) an adaptor protein, B cell linker protein (BLNK); and (4) the surrogate light chain, ?5/14.1 (see Table 114–1).

Clinical Manifestations.

Most boys afflicted with XLA remain well during the first 6–9 mo of life by virtue of maternally transmitted IgG antibodies. Thereafter, they acquire infections with extracellular pyogenic organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, unless given prophylactic antibiotics or immunoglobulin therapy. Infections with *Mycoplasma* are also particularly problematic for these patients. Chronic fungal infections are not usually present, and *Pneumocystis carinii* pneumonia rarely occurs unless there is an associated neutropenia. Viral infections are also usually handled normally, with the exceptions

Figure 114-1 Location of mutations in the functional domains of the BTK protein. Deletion and point mutations in BTK identified to date in many boys with classic XLA are in the kinase domain, whereas CBA/N xid mice with a less severe B-cell defect have a point mutation causing an amino acid substitution at position 28 in the N-terminal domain. A male with a less severe B-cell defect than in classic XLA has had a point mutation at position 361 in the SH2 domain. However, more recently boys with classic XLA are also reported to have mutations at the xid mutation site and in the SH2 domain. (From Buckley RH: Breakthroughs in the understanding and therapy of primary immunodeficiency. *Pediatr Clin North Am* 1994;41:665–90.)

of hepatitis viruses and enteroviruses. Several examples of paralysis after live polio vaccine administration have occurred, and chronic, eventually fatal central nervous system infections with various echoviruses have occurred in more than 45 patients. These observations suggest a primary role for antibody, particularly secretory IgA, in host defense against enteroviruses, because normal T-cell function has been present in X-linked agammaglobulinemic patients with such persistent infections. Growth hormone deficiency has also been reported in association with XLA.

The diagnosis of XLA should be suspected if lymphoid hypoplasia is found on physical examination (minimal or no tonsillar tissue and no palpable lymph nodes) and serum concentrations of IgG, IgA, IgM, and IgE are far below the 95% confidence limits for appropriate age- and race-matched controls (Chapter 710), usually <100?mg/dL total immunoglobulin. Tests for natural antibodies to type A and

B red blood cell polysaccharide antigens (isohemagglutinins) and for antibodies to antigens given during routine immunizations are abnormal in this disorder, whereas they are normal in transient hypogammaglobulinemia of infancy. Flow cytometry is an important test to demonstrate the absence of circulating B cells, which will distinguish this disorder from common variable immunodeficiency.

COMMON VARIABLE IMMUNODEFICIENCY

Common variable immunodeficiency (CVID) is a syndrome characterized by hypogammaglobulinemia with phenotypically normal B cells. It is also known as **acquired hypogammaglobulinemia** because of a generally later age of onset of infections. CVID patients may appear similar clinically to those with XLA in the kinds of infections experienced and bacterial etiologic agents involved, except that echovirus meningoencephalitis is rare in patients with CVID. In contrast to XLA, the sex distribution in CVID is almost equal, the age of onset is later, and infections are less severe.

Genetics and Pathogenesis.

Most patients, if not all, have no identified molecular diagnosis. CVID is a “wastebasket” category of primary immunodeficiency disorders that likely consists of several different genetic defects. As the molecular bases of more and more primary immunodeficiency syndromes are identified, it will be important to consider a variety of genetic mutations that can lead to the hypogammaglobulinemia seen in CVID, including mutations in the *Btk, SH2D1A, CD40L, CD40*, and *AID* genes.

Because CVID occurs in first-degree relatives of patients with selective IgA deficiency, and some patients with IgA deficiency later become panhypogammaglobulinemic, these diseases may have a common genetic basis. The high incidence of abnormal immunoglobulin concentrations, autoantibodies, autoimmune disease, and malignancy in both types of patients and in their families also suggests a shared hereditary influence. This concept is supported by the discovery of a high incidence of C4-A gene deletions and C2 rare gene alleles in the class III major histocompatibility complex (MHC) region in individuals with either IgA deficiency or CVID, suggesting that a common susceptibility gene is in this region on chromosome 6. A small number of HLA haplotypes are shared by individuals affected with IgA deficiency and CVID, with at least one of two particular haplotypes being present in 77% of those affected. In one large family with 13 members, two had IgA deficiency and three had CVID. All of the immunodeficient patients in the family had at least one copy of an MHC haplotype that is abnormally frequent in IgA deficiency and CVID: HLA-DQB1 *0201, HLA-DR3, C4B-Sf, C4A-deleted, G11-15, Bf-0.4, C2a, HSP70-7.5, TNFa-5, HLA-B8, and HLA-A1. However, four immunologically normal members of the pedigree also possessed this haplotype, indicating that its presence is not sufficient for expression of the defects. Environmental factors, particularly drugs such as phenytoin, d-penicillamine, gold, and sulfasalazine are

suspected to be triggers for disease expression in individuals with the permissive genetic background.

Despite normal numbers of circulating immunoglobulin-bearing B lymphocytes and the presence of lymphoid cortical follicles, blood B lymphocytes from CVID patients do not differentiate normally into immunoglobulin-producing cells when stimulated with pokeweed mitogen (PWM) in vitro, even when co-cultured with normal T cells. However, studies have shown that CVID B cells can be stimulated both to switch isotype and to synthesize and secrete some immunoglobulin when stimulated with anti-CD40 and IL-4 or IL-10. T cells and T-cell subsets are usually present in normal percentages, although T-cell function is depressed in some patients.

Clinical Manifestations.

The serum immunoglobulin and antibody deficiencies in CVID may be as profound as in XLA. Patients with CVID often have autoantibody formation and normal-sized or enlarged tonsils and lymph nodes, and approximately 25% of patients have splenomegaly. CVID has also been associated with a sprue-like syndrome, with or without nodular follicular lymphoid hyperplasia of the intestine; thymoma; alopecia areata; hemolytic anemia; gastric atrophy; achlorhydria; and pernicious anemia. Lymphoid interstitial pneumonia, pseudolymphoma, B-cell lymphomas, amyloidosis, and noncaseating sarcoid-like granulomas of the lungs, spleen, skin, and liver also occur. There is a 438-fold increase in lymphomas among affected women in the 5th and 6th decades of life. CVID is reported to resolve transiently or permanently in patients who acquire human immunodeficiency virus (HIV) infection.

SELECTIVE IgA DEFICIENCY

An isolated absence or near absence (<10?mg/dL) of serum and secretory IgA is the most common well-defined immunodeficiency disorder, with a frequency of 0.33% reported among some apparently healthy blood donors. However, this condition is also commonly associated with ill health.

Genetics and Pathogenesis.

As is the case for CVID, the basic defect leading to IgA deficiency is unknown. Phenotypically normal blood B cells are present in both conditions. IgA deficiency occasionally remits spontaneously or after discontinuation of phenytoin (Dilantin) therapy. The occurrence of IgA deficiency in both males and females and in members of successive generations within families suggests autosomal dominant inheritance with variable expressivity. This defect also commonly occurs in pedigrees containing individuals with CVID. Indeed, IgA deficiency has been noted to evolve into CVID, and the finding of rare alleles and deletions of MHC class III genes in both conditions suggests that the susceptibility gene common to these two conditions may reside in the MHC class III region on chromosome 6. IgA deficiency is noted in patients treated with the same drugs associated with producing CVID (phenytoin, d-penicillamine, gold, and sulfasalazine), suggesting that environmental factors may also trigger this disease.

Clinical Manifestations.

Infections occur predominantly in the respiratory, gastrointestinal, and urogenital

tracts. Bacterial agents responsible are the same as in other antibody deficiency syndromes. Children with IgA deficiency vaccinated with killed poliovirus intranasally produce local IgM and IgG antibodies. Serum concentrations of other immunoglobulins are usually normal in patients with selective IgA deficiency, although IgG2 (and other) subclass deficiency is reported, and IgM (usually elevated) may be monomeric.

Patients with IgA deficiency often have IgG antibodies against cow's milk and ruminant serum proteins. These antiruminant antibodies may cause false-positive results in immunoassays for IgA that use goat (but not rabbit) antisera. A sprue-like syndrome occurs in adults with this defect, which may or may not respond to a gluten-free diet. High incidences of autoantibodies and autoimmune diseases are noted, and the incidence of malignancy is increased. Serum antibodies to IgA are reported in as many as 44% of patients with selective IgA deficiency. If these antibodies are of the IgE isotype, they can cause severe or fatal anaphylactic reactions after intravenous administration of blood products containing IgA. For this reason, only five-times washed (in 200-mL volumes) normal donor erythrocytes, or blood products from other IgA-deficient individuals, should be administered to these patients. Administration of intravenous immunoglobulin (IVIG), which is greater than 99% IgG, is not indicated because most IgA-deficient patients make IgG antibodies normally. Moreover, many IVIG preparations contain sufficient IgA to cause anaphylactic reactions.

TRANSIENT HYPOGAMMAGLOBULINEMIA OF INFANCY

After birth, the serum level of IgG in an infant diminishes with the decline of maternally derived IgG antibodies, reaching a nadir at 3–4 mo of age, and then rises as an infant's own IgG production gradually increases. Transient hypogammaglobulinemia of infancy (THI) is an extension of this physiologic hypogammaglobulinemia beyond 6 mo of age. B and T lymphocytes are present in normal numbers, and T lymphocyte function is normal. Unlike patients with XLA or CVID, patients with THI synthesize antibodies to type A and B red blood cell polysaccharide antigens (isohemagglutinins) and to diphtheria and tetanus toxoids normally, usually by 6–11 mo of age, and well before total immunoglobulin concentrations become normal. This condition likely represents the extremes of normal variability of the immune system. THI patients may have an increased frequency of otitis media and sinusitis, but infections are not life threatening and respond to appropriate antimicrobial therapy. IVIG therapy is not indicated in this condition.

IgG SUBCLASS DEFICIENCIES

Some patients have deficiencies of one or more of the four subclasses of IgG despite normal or elevated total IgG serum concentration. Most patients with absent or very low concentrations of IgG2 also have IgA deficiency. Other patients with IgG2 deficiency have an evolving pattern of immunodeficiency, such as CVID, suggesting that the presence of IgG subclass deficiency may be a marker for more generalized immune dysfunction. The biologic significance of the numerous moderate deficiencies of IgG subclasses that have been reported is difficult to assess, particularly because commercial laboratory measurement of IgG subclasses is problematic. The more relevant issue is a patient's capacity to make specific antibodies to protein and polysaccharide antigens, because profound deficiencies of antipolysaccharide antibodies have been noted even in the presence of normal concentrations of IgG2. IVIG should not be administered to patients with IgG subclass deficiency unless they are shown to have a deficiency of antibodies to a broad array of antigens.

IMMUNOGLOBULIN HEAVY- AND LIGHT-CHAIN DELETIONS

Some completely asymptomatic individuals have been documented to have a total absence of IgG1, IgG2, IgG4, and/or IgA1 due to gene deletions. These abnormalities were discovered fortuitously in 16 individuals, 15 of whom had no history of undue susceptibility to infection, and all of whom produced antibodies of all other isotypes in normal quantities. These patients illustrate the importance of assessing specific antibody formation before deciding to initiate IVIG therapy in IgG subclass–deficient patients.

HYPER IgM SYNDROME

The hyper IgM syndrome is genetically heterogeneous. Causative mutations have been identified in 2 genes on the X chromosome, the CD40 ligand and NEMO genes, and 2 genes on autosomal chromosomes, the AID gene on chromosome 12 and

the CD40 gene on chromosome 20. Distinctive clinical features permit presumptive recognition of the type of mutation in these patients, thereby aiding proper choice of therapy. However, all such patients should undergo molecular analysis to ascertain the affected gene for purposes of genetic counseling, carrier detection, and definitive therapy.

X-Linked Hyper IgM due to Mutations in the CD40 Ligand (CD154) Gene

Boys with this syndrome have very low serum concentrations of IgG and IgA, with a usually normal or sometimes elevated concentration of polyclonal IgM, very small tonsils, no palpable lymph nodes, and often profound neutropenia.

Genetics and Pathogenesis.

B cells from boys with the CD40 ligand defect are capable of synthesizing not only IgM but also IgA and IgG when co-cultured with a “switch” T-cell line, indicating that the B cells are actually normal in this condition and that the defect is in the T cells. The abnormal gene is localized to Xq26, and the gene product, CD154, is the ligand for CD40, which is present on B cells and monocytes. CD154 is upregulated on activated T cells. Mutations in CD154 on activated CD4 T cells from males with this defect result in an inability to signal B cells to undergo isotype switching, and thus they produce only IgM. The failure of T cells to interact with B cells through this receptor-ligand pair also causes a failure of upregulation of the B cell and monocyte surface molecules CD80 and CD86 that interact with CD28/CTLA4 on T cells, resulting in failure of “cross-talk” between immune system cells. The failure of

interaction of the molecules of those pathways results in a propensity for tolerogenic T cell signaling and defective recognition of tumor cells. More than 73 distinct point mutations or deletions in the gene encoding CD154 have been identified in 87 unrelated families, giving rise to frame shifts, premature stop codons, and single amino acid substitutions, most of which were clustered in the domain with homology to tumor necrosis factor (TNF), located in the carboxy-terminal region.

Clinical Manifestations.

Similar to patients with XLA, boys with the CD40 ligand defect have small tonsils and often no palpable lymph nodes, and become symptomatic during the 1st or 2nd year of life with recurrent pyogenic infections, including otitis media, sinusitis, pneumonia, and tonsillitis. Lymph node histology shows only abortive germinal center formation and a severe depletion and phenotypic abnormalities of follicular dendritic cells. However, in contrast to patients with XLA, these patients have normal numbers of circulating B lymphocytes, have a marked susceptibility to *P. carinii* pneumonia, and are often profoundly neutropenic. Circulating T cells are also present in normal number and in vitro responses to mitogens are normal, but there is decreased antigen-specific T-cell function. In a recent retrospective study of 56 patients with the CD40 ligand defect, 13 (23.3%) had died at a mean age at death of 11.7 years. In addition to opportunistic infections such as *P. carinii* pneumonia, there is an increased incidence of extensive verruca vulgaris lesions, *Cryptosporidium* enteritis, subsequent liver disease, and increased risk of malignancy. Because of the poor prognosis, the treatment of choice is an HLA-identical bone marrow transplant at an early age. Alternative treatment for this condition is monthly infusion of IVIG. In some patients with severe neutropenia, the use of G-CSF has been beneficial.

X-Linked Hyper IgM due to Mutations in the Gene Encoding Nuclear Factor ?B (NF-?B) Essential Modulator (NEMO or Ikk?) Deficiency

This is a newly recognized syndrome characterized most often clinically as anhidrotic **ectodermal dysplasia with associated immunodeficiency (EDA-ID)** in males. The condition results from mutations in the IKBKG gene at position 28q on the X chromosome that encodes **nuclear factor of ?B (NF-?B) essential modulator (NEMO)**. Germ line loss-of-function mutations cause the X-linked dominant condition incontinentia pigmenti in females and are lethal in male fetuses. Mutations in the coding region of IKBKG are associated with EDA-ID. The immunodeficiency is variable, with most patients showing impaired antibody responses to polysaccharide antigens. However, some patients with EDA-ID have hyper IgM. Pharmacologic inhibitors of NF-?B activation have been shown to downregulate CD154 mRNA and protein levels, suggesting the mechanism of hyper IgM in this condition. The hyper IgM patients with this defect should be easily recognizable because of the presence of ectodermal dysplasia.

Autosomal Recessive Hyper IgM due to Mutations in the Gene for Activation-Dependent Cytidine Deaminase (AID)

Not all males with hyper IgM have mutations in the gene encoding CD154 or NFKB, and there are many examples in females, indicating that this condition has other causes.

Genetics and Pathogenesis.

Patients with autosomal hyper IgM usually have normal numbers of circulating B lymphocytes but, in contrast to patients with the CD40 ligand defect, B cells from these patients are not able to switch from IgM-secreting to IgG-, IgA-, or IgE-secreting cells, even when co-cultured with monoclonal antibodies to CD40 and a variety of cytokines. When their B cells are cultured in vitro, they spontaneously secrete large amounts of IgM, but this is not further augmented by the addition of IL-4 or anti-CD40 with IL-4 or other cytokines. Thus, in these patients, there is truly an intrinsic B-cell abnormality. The defect in many such patients has recently been identified as mutations in a gene on chromosome 12p13 that encodes an activation-dependent cytidine deaminase (AID), an RNA-editing enzyme specifically expressed in germinal center B cells. Deficiency of AID results in impaired terminal differentiation of B cells, a failure of isotype switching, and lack of immunoglobulin gene somatic hypermutation. Unlike patients with X-linked hyper-IgM, who have minimal lymphoid tissue, patients with a mutation of AID have lymphoid hyperplasia because they have enhanced, although defective, germinal center formation.

Clinical Manifestations.

As with the X-linked defects, concentrations of serum IgG, IgA, and IgE are very low in the autosomal recessive form of hyper IgM. However, in contrast to the CD40 ligand defect, the serum IgM concentration in patients with autosomal recessive hyper IgM is usually markedly elevated and polyclonal. Patients with AID mutations are generally older at age of onset, do not have susceptibility to *P. carinii* pneumonia, often do have isohemagglutinins, and are much less likely to have neutropenia unless it occurs on an autoimmune basis. With early diagnosis and monthly infusions of IVIG, as well as good management of infections with antibiotics, patients with AID mutations generally have a more benign course than do boys with the CD40 ligand defect.

Autosomal Recessive Hyper IgM due to Mutations in CD40

Patients with autosomal recessive hyper IgM were recently identified who failed to express CD40 on their B-cell surfaces resulting from mutations in the CD40 gene. CD40 is a type I integral membrane glycoprotein encoded by a gene on chromosome 20 and belonging to the TNF and nerve growth factor receptor superfamily. It is expressed on B cells, macrophages, dendritic cells, and a few other types of cells. Mutations in the CD40 gene cause an autosomal recessive form of hyper IgM that is clinically indistinguishable from hyper IgM resulting from the

---

X-linked CD40 ligand (CD154) defect. However, in contrast to the CD40 ligand defect, the B cells in the autosomal recessive condition are intrinsically abnormal and cannot isotype switch. The T cells are normal except to the extent that they cannot cause upregulation of CD80 and CD86 on B cells and macrophages to interact with CD28/CTLA4 on T cells.

X-LINKED LYMPHOPROLIFERATIVE DISEASE

X-linked lymphoproliferative (XLP) disease, also referred to as **Duncan disease** after the original kindred in which it was described, is an X-linked recessive trait characterized by an inadequate immune response to infection with Epstein-Barr virus (EBV).

Genetics and Pathogenesis.

The defective gene in XLP was localized to Xq25, cloned, and initially named SAP (for SLAM Associated Protein) but is now known officially as **SH2D1A**. SLAM (signaling lymphocyte activation molecule) is an adhesion molecule that is upregulated on both T and B cells with infection and other stimulation. SH2D1A is highly expressed in thymocytes and peripheral blood T and NK cells, with a prevalent expression on Th1 cells; its presence in B lymphocytes is unclear. Thus, although antibody deficiency is frequently present, this is really a T and NK cell defect. SH2D1A competes with SHP-2 for binding to SLAM and, as such, is a regulatory molecule. In XLP patients the absence of SH2D1A can lead to an uncontrolled cytotoxic T-cell immune response to EBV. The SH2D1A protein permissively associates with 2B4 on NK cells; thus, selective impairment of 2B4-mediated NK cell activation also contributes to the immunopathology of XLP.

Clinical Manifestations.

Affected males are usually healthy until they acquire EBV infection. The mean age of presentation is less than 5 yr. There are 3 major clinical phenotypes: (1) fulminant, often fatal, infectious mononucleosis (50% of cases); (2) lymphomas, predominantly involving B lineage cells (25%); or (3) acquired hypogammaglobulinemia (25%). There is a marked impairment in production of antibodies to the EBV nuclear antigen (EBNA), whereas titers of antibodies to the viral capsid antigen have ranged from absent to markedly elevated. XLP overall has an unfavorable prognosis, inasmuch as 70% of affected boys die by age 10. Only two XLP patients are known to have survived beyond 40 years. Unless there is a family history of XLP, diagnosis prior to the onset of complications is difficult because affected individuals are asymptomatic initially. It is possible to identify affected males of affected kindreds through mutation analysis before they develop primary EBV infection. Approximately half of the limited number of patients with XLP given HLA-identical related or unrelated unfractionated bone marrow transplants are currently surviving without signs of the disease.

Two pedigrees have been reported in which boys in one arm of each pedigree were diagnosed with common variable immunodeficiency (CVID), whereas those in the other arms had fulminant infectious mononucleosis. The family members with CVID never gave a history of infectious mononucleosis. However, all affected members of each pedigree had the same distinct SH2D1A mutation despite the different clinical phenotypes. Because the SH2D1A mutation was the same but the phenotype varied in these families, XLP should be considered in all males with a diagnosis of CVID, particularly if there is more than one male family member with this phenotype.

114.1 Treatment of B-Cell Defects

Except for the CD40 ligand defect and XLP, for which bone marrow transplantation is recommended, judicious use of antibiotics and regular administration of antibodies are the only effective treatments for B-cell disorders. The most common form of replacement therapy is with IVIG. Broad antibody deficiency should be carefully documented before such therapy is initiated. The rationale for the use of these preparations is to provide missing antibodies, not to raise the serum IgG or IgG subclass level. The development of safe and effective IVIG is a major advance in the treatment of patients with severe antibody deficiencies, although it is expensive and there have been frequent national shortages. Almost all commercial preparations are isolated from normal plasma by the Cohn alcohol fractionation method or a modification of this method. Cohn fraction II is then further treated to remove aggregated IgG. Additional stabilizing agents such as sugars, glycine, and albumin are added to prevent re-aggregation and protect the IgG molecule during lyophilization. The ethanol used in preparation of immune serum globulin and IVIG inactivates HIV; an organic solvent/detergent step inactivates hepatitis B and C viruses. Most commercial lots are produced from plasma pooled from more than 60,000 donors and therefore contain a broad spectrum of antibodies. Each pool must contain adequate levels of antibody to antigens in various vaccines, such as tetanus and measles. However, there is no standardization based on titers of antibodies to more clinically relevant organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae* type b.

The IVIG preparations available in the United States have similar efficacy and safety. Rare transmission of hepatitis C virus has occurred in the past but the potential transmission of hepatitis C virus has been resolved by additional treatment with an organic solvent/detergent mixture. There has been no documented transmission of HIV by any of these preparations. IVIG (400?mg/kg/mo) achieves trough IgG levels close to the normal range. Systemic reactions to IVIG may occur, but rarely are these true anaphylactic reactions. Anaphylactic reactions caused by a patient's IgE antibodies to IgA in the IVIG preparation may occur, however, in patients with CVID or IgA deficiency. All newly diagnosed patients with CVID should be screened for anti-IgA antibodies through the American Red Cross before undergoing IVIG therapy. If anti-IgA antibodies are detected, IVIG therapy may still be possible by use of carefully screened lots of the one available IVIG preparation containing almost no IgA (Gammagard S/D, Baxter).

Chapter 115 - Primary Defects of Cellular Immunity

In general, patients with defects in T-cell function have infections or other clinical problems that are more severe than in patients with antibody deficiency disorders. These individuals rarely survive beyond infancy or childhood. The defective gene products for some primary T-cell diseases have been identified

(Table 115–1). Transplantation of thymic tissue or of major histocompatibility complex (MHC)–compatible sibling or haploidentical (half-matched) parental bone marrow are currently the treatments of choice for patients with fatal T-cell defects (Chapter 116.3).

THYMIC HYPOPLASIA (DiGEORGE SYNDROME)

Thymic hypoplasia results from dysmorphogenesis of the 3rd and 4th pharyngeal pouches during early embryogenesis, leading to hypoplasia or aplasia of the thymus and parathyroid glands. Other structures forming at the same age are also frequently affected, resulting in anomalies of the great vessels (right-sided aortic arch), esophageal atresia, bifid uvula, congenital heart disease (conotruncal, atrial, and ventricular septal defects), a short philtrum of the upper lip, hypertelorism, an antimongoloid slant to the eyes, mandibular hypoplasia, and low-set, often notched ears. The diagnosis is often first suggested by hypocalcemic seizures during the neonatal period. Similar facial features and conotruncal heart lesions are seen in the fetal alcohol syndrome.

Genetics and Pathogenesis.

DiGeorge syndrome occurs in both males and females. Because familial occurrence is rare, the defect was thought unlikely to be heritable. However, microdeletions of specific DNA sequences from chromosome 22q11.2, the DiGeorge chromosomal region (DGCR), are found in more than 95% of cases. Several candidate genes have been identified in this region. There appears to be an excess of 22q11.2 deletions of maternal origin. Polymerase chain reaction (PCR)–based genotyping using microsatellite DNA markers located within the commonly deleted region permits rapid detection of such microdeletions. Similarities are observed between the DiGeorge syndrome, the velocardiofacial syndrome (VCFS), and the conotruncal anomaly face syndrome (CTAFS), inasmuch as all three have conotruncal heart defects and 22q deletions. The **CATCH 22 syndrome** (*C*ardiac, *A*bnormal facies, *T*hymic Hypoplasia,

*C*left palate, *H*ypocalcemia) includes the broad clinical spectrum of conditions with 22q11.2 deletions. Other deletions associated with DiGeorge and velocardiofacial syndromes have been identified on chromosome 10p13 (also see Chapter 70).

Concentrations of serum immunoglobulins are usually normal, but IgA may be diminished and IgE elevated. Absolute lymphocyte counts are usually only moderately low for age. The CD3 T-cell counts are variably decreased in number, corresponding to the degree of thymic hypoplasia, and as a result the percentage of B cells is increased. Lymphocyte responses to mitogen stimulation are absent, reduced, or normal, depending on the degrees of thymic deficiency. Thymic tissue, when found, contains Hassall corpuscles, normal density of thymocytes, and corticomedullary distinction. Lymphoid follicles are usually present, but lymph node paracortical areas and thymus-dependent

TABLE 115-1 -- **Primary Cellular Immunodeficiency Diseases**

Chromosome and Region	Gene Product	Disorder	Functional Deficiencies
2q12	ZAP-70*	CD8 lymphocytopenia	Failure of CD4 T cells to respond to usual signals
10p13	Unknown	Thymic hypoplasia (DiGeorge syndrome)/velocardiofacial syndrome	Low number of T cells and impaired T-cell function
11	CD3 ?* or e*	CD3 deficiency	Poor T-cell responses to mitogens; lack of cytotoxic T cells; IgG subclass deficiency
22q11.22	Unknown	Thymic hypoplasia (DiGeorge syndrome)/velocardiofacial syndrome	Low number of T cells and impaired T-cell function

**Gene cloned and sequenced, gene product known.*

regions of the spleen show variable degrees of depletion.

Clinical Manifestations.

Variable hypoplasia of the thymus and parathyroid glands is more frequent than total aplasia. Children with variable hypoplasia are referred to as having **partial DiGeorge syndrome;** they may have little trouble with infections and grow normally. Patients with **complete DiGeorge syndrome** resemble patients with severe combined immunodeficiency (SCID) in their susceptibility to infections with low-grade or opportunistic pathogens, including fungi, viruses, and *P. carinii*, and to graft versus host disease (GVHD) from nonirradiated blood transfusions.

Treatment.

The immune deficiency in the complete DiGeorge syndrome has been corrected by cultured unrelated thymic tissue transplants and by unfractionated HLA-identical sibling bone marrow transplantation (Chapter 116.3).

DEFECTIVE EXPRESSION OF THE T-CELL RECEPTOR–CD3 COMPLEX (TI-CD3)

The first type of this disorder was found in two brothers in a Spanish family. The proband presented with severe infections and died at 31 mo of age with autoimmune hemolytic anemia and viral pneumonia. His lymphocytes had responded poorly to mitogens and to anti-CD3 in vitro and could not be stimulated to develop cytotoxic T cells. However, his antibody responses to protein antigens had been normal, indicating normal T-helper cell function. His 12-yr-old brother was healthy but had almost no CD3-bearing T cells, and had IgG2 deficiency similar to his sibling. The defect in this family is due to mutations in the CD3e chain.

The second type of this disorder was diagnosed in a 4-yr-old French boy who had recurrent *Haemophilus influenzae* pneumonia and otitis media in early life but is now healthy. He has a partial defect in expression of Ti-CD3, and thus the percentage of CD3 cells is about half-normal but the level of expression is markedly decreased. His T cells do not proliferate in response to anti-CD3 or anti-CD2, nor do they express the IL-2 receptor or have normal calcium influx after these treatments. However, they do respond normally to stimulation with anti-CD28 or antigens, such as tetanus toxoid. The defect was shown to be due to two independent CD3e gene mutations, leading to defective CD3e chain synthesis and preventing normal association and membrane expression of the TCR/CD3 complex.

DEFECTIVE CYTOKINE PRODUCTION

Only a few defects of cytokine production are known. One is a selective inability to produce IL-2. In the two reported cases, patients had severe recurrent infections in infancy. The IL-2 gene was present in both, but no IL-2 message or protein was produced. Other T-cell cytokines were produced normally.

Another type was found in a single patient who also presented during infancy with severe recurrent infections and failure to thrive. She had defective transcription of several lymphokine genes, including IL-2, IL-3, IL-4, and IL-5, possibly resulting of abnormal binding of nuclear factor of activated T cells (NFAT-1) to response elements in IL-2 and IL-4 enhancers. She was treated with recombinant IL-2 with some clinical improvement.

IL-12, which is produced by activated antigen-presenting cells, promotes the development of Th1 responses and is a powerful inducer of IFN-? production by T and natural killer (NK) cells. A child with bacille Calmette-Guérin and *Salmonella*

enteritidis infections was found to have a large homozygous deletion within the IL-12 p40 subunit gene, precluding expression of functional IL-12 p70 cytokine by activated dendritic cells and phagocytes. As a result, IFN-? production by the child's lymphocytes was markedly impaired. This suggested that IL-12 is essential for protective immunity to intracellular bacteria such as *Mycobacterium* and *Salmonella*.

T-CELL ACTIVATION DEFECTS

T-cell activation defects are characterized by the presence of normal or elevated numbers of blood T cells that appear phenotypically normal but that fail to proliferate or produce cytokines in response to stimulation with mitogens, antigens, or other signals delivered to the T-cell antigen receptor (TCR), owing to defective signal transduction from the TCR to intracellular metabolic pathways. These patients have problems similar to those of other T-cell–deficient individuals, and some with severe T-cell activation defects may resemble SCID patients clinically.

CD8 LYMPHOCYTOPENIA DUE TO MUTATIONS IN THE GENE ENCODING ZETA-ASSOCIATED PROTEIN 70

Patients with this T-cell activation defect present during infancy with severe, recurrent, and often fatal infections. The majority of cases are reported among Mennonites. These patients have normal or elevated numbers of blood B cells and low to elevated serum immunoglobulin concentrations. Their blood lymphocytes exhibit normal expression of the T-cell surface antigens CD3 and CD4, but CD8 cells are almost totally absent. These cells fail to respond to mitogens or to allogeneic cells in vitro or to generate cytotoxic T lymphocytes. By contrast, NK activity is normal. The thymus of one patient exhibited normal architecture with normal numbers of CD4:CD8 double-positive thymocytes but an absence of CD8 single-positive thymocytes. This condition is due to mutations in the gene encoding **zeta-associated protein 70 (ZAP-70)**, a non-*src* family protein tyrosine kinase important in T-cell signaling, which is localized to chromosome 2q12. The normal number of CD4:CD8 double-positive T cells is because the thymocytes can use the other member of the same tyrosine kinase family, *Syk*, to facilitate positive selection. *Syk* is present at fourfold higher levels in thymocytes than in peripheral T cells, possibly accounting for the lack of normal responses by the CD4 blood T cells.

P56 *LCK* DEFICIENCY

A 2 mo old male infant who presented with bacterial, viral, and fungal infections was found to be lymphopenic and hypogammaglobulinemic. B and NK cells were present, but there was a low number of CD4 T cells. Mitogen responses were variable. The T cells failed to express the activation marker CD69 when stimulated through the T-cell receptor but did when stimulated with phorbol myristate acetate and a calcium ionophore, suggesting a proximal signaling defect. Molecular studies revealed an alternatively spliced transcript for p56 *lck* that lacked the kinase domain.

Chapter 116 - Primary Combined Antibody and Cellular Immunodeficiencies

Patients with combined antibody and cellular defects have severe, frequently opportunistic infections that lead to death in infancy or childhood unless they are provided bone marrow transplantation early in life. These are thought to be rare defects; however, the true incidences are unknown because there is no screening for any of these defects during infancy. It is possible that many die of infection without being diagnosed. The defective gene products for many combined immunodeficiencies have been identified (Table 116–1).

116.1 Severe Combined Immunodeficiency (SCID)

The syndromes of SCID are caused by diverse genetic mutations that lead to absence of all adaptive immune function and, in some cases, in a lack of natural killer (NK) cells (see Table 116–1). Patients with this group of disorders have the most severe of all of the recognized immunodeficiencies.

Pathogenesis.

Typically, patients with SCID have very small thymuses (<1?g) that usually fail to descend from the neck, contain few thymocytes, and lack corticomedullary distinction and Hassall corpuscles. The thymic epithelium appears histologically normal. Both the follicular and paracortical areas of the spleen are depleted of lymphocytes. Lymph nodes, tonsils, adenoids, and Peyer patches are absent or extremely underdeveloped.

Clinical Manifestations.

Affected infants present within the first few months of life with diarrhea, pneumonia, otitis media, sepsis, and cutaneous infections. Growth may appear normal initially, but extreme wasting usually ensues after diarrhea and infections begin. Persistent infections with opportunistic organisms such as *Candida albicans, P. carinii*, varicella, measles, parainfluenza 3, CMV, Epstein-Barr virus (EBV), adenovirus, and bacillus Calmette-Guérin (BCG) lead to death. Affected infants also lack the ability to reject foreign tissue and are therefore at risk for graft versus host disease (GVHD) from maternal immunocompetent T cells crossing the placenta, or from T lymphocytes in nonirradiated blood products or allogeneic bone marrow.

Infants with SCID have lymphopenia (<2000/mm^3)that is present at birth, indicating that the condition could be diagnosed in all affected infants if white blood cell counts with manual differential counts were routinely performed on all cord bloods. These infants also have an absence of lymphocyte

TABLE 116.1-1 -- Combined Immunodeficiency Disorders

Chromosome and Region	Gene Product	Disorder	Functional Deficiencies
1q[*]	RFX5	MHC class II antigen deficiency	Low immunoglobulins, lack of T-cell responses to antigens, CD4 deficiency
5p 13[*]	IL-7Ra	T-, B+, NK+ SCID	Absence of T and B cell functions
6p21.3[*]	TAP1, TAP2	MHC class I antigen deficiency	Marked deficiency of CD8 T cells; combined B- and T-cell defects
6q22–q23[*]	IFN-? R1	Disseminated mycobacterial infections	Failure of macrophages and other cells to produce TNF-a in response to IFN-?
9p21–p13	Endoribonuclease RNase MRP	Cartilage-hair hypoplasia	Combined B- and T-cell defects of varying severity (including defective antibody-mediated immunity, CID, and SCID)
10p13[*]	Artemis	T-, B-, NK + SCID	Absence of T and B cell functions
10p14–p15[*]	IL2Ra	Lymphoproliferative syndrome	Poor T-cell responses; impaired apoptosis; increased *bci*-2; utoimmunity
11p13[*]	RAG1 or RAG2	T-, B-, NK + SCID	Absence of T and B cell functions
11q22.3[*]	DNA-dependent kinase	Ataxia-telangiectasia	Selective IgA deficiency; T-cell deficiency
13q[*]	RFXAP	MHC class II antigen deficiency	Low immunoglobulins, lack of T-cell responses to antigens, CD4 deficiency

14q13.1*	Purine nucleosidase	PNP deficiency	Severe T-cell deficiency; may have immunoglobulins
16p13*	CIITA	MHC class II antigen deficiency	Low immunoglobulins, lack of T-cell responses to antigens, CD4 deficiency
19p13.1*	Jak3	T-, B+, NK- SCID	Absence of T-, B- and NK-cell functions
20q13.11*	ADA	T-, B-, NK- SCID	Absence of T- and B-cell functions
Xp11.23*	WASP	Wiskott-Aldrich syndrome	Thrombocytopenia; poor antipolysaccharide antibody production; T-cell deficiency
Xq13.1*	Common ? chain (?c)	T-, B+, NK- SCID	Absence of T-, B- and NK-cell functions

WASP = Wiskott-Aldrich syndrome protein; TH1 = T-helper cell type 1; TH2 = T-helper cell type 2; PNP = purine nucleoside phosphorylase; IL2Ra = interleukin 2 receptor a chain; ADA = adenosine deaminase; Jak3 = Janus kinase 3; IL7Ra = interleukin 7 receptor a chain; RAG1 and RAG2 = recombinase activating genes 1 and 2; IFN-?R1 = interferon ? receptor chain 1; IL-12R ß 1 = interleukin 12 receptor ß 1 chain; MHC = major histocompatibility complex; SCID = severe combined immunodeficiency; TAP = transporter of antigenic peptide; CIITA = class II transactivator.

*Gene cloned and sequenced, gene product known.

proliferative responses to mitogens, antigens, and allogeneic cells in vitro. Patients with adenosine deaminase (ADA) deficiency have the lowest absolute lymphocyte counts, usually <500/mm^3 . Serum immunoglobulin concentrations are diminished to absent, and no antibodies are formed after immunizations. Analyses of lymphocyte populations and subpopulations demonstrate distinctive phenotypes for the various genetic forms of SCID. T cells are extremely low or absent in all types; when detected, they are in most cases transplacentally derived maternal T cells.

Treatment.

This is a true pediatric emergency. Unless immunologic reconstitution is achieved through bone marrow transplantation, death usually occurs in the 1st yr of life and almost invariably before the end of the 2nd yr. If diagnosed at birth or within the first 3 mo of life, more than 95% of cases can be treated successfully with HLA-identical or T-cell–depleted haploidentical (half-matched) related bone marrow stem cells without the need for pretransplant chemoablation or post-transplant GVHD prophylaxis. Recent success in treating X-linked SCID by gene therapy in both Paris and London offers hope that gene therapy will eventually be the treatment of choice for some if not all forms of SCID for which the molecular bases have been identified.

X-LINKED SEVERE COMBINED IMMUNODEFICIENCY (SCIDX1) DUE TO MUTATIONS IN THE GENE ENCODING THE COMMON CYTOKINE RECEPTOR GAMMA CHAIN ($?_c$)

X-linked SCID (SCIDX1) is the most common form of SCID in the United States, accounting for approximately 45% of cases. Clinically, immunologically, and histopathologically, affected individuals appear similar to those with other forms of SCID except for having uniformly low percentages of T and NK cells and an elevated percentage of B cells (T-, B+, NK-), a characteristic feature shared only with Janus kinase 3 (Jak3)–deficient patients with SCID. The abnormal gene in SCIDX1 was mapped to Xq13, cloned, and found to encode the common ? ($?_c$) chain for several cytokine receptors, including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. The shared $?_c$ chain functions both to increase the affinity of the receptor for the respective cytokine and to enable the receptors to mediate intracellular signaling. Incapacitation of the receptors for all of these developmentally crucial cytokines by genetic mutations in the common ? chain provides an explanation for the severity of the immunodeficiency in SCIDX1. In the first 136 patients studied, 95 distinct mutations spanning all 8 IL2RG exons were identified, most of them consisting of small changes at the level of one to a few nucleotides. These mutations resulted in abnormal $?_c$ chains in two thirds of the cases and absent $?_c$ protein in the remainder. Carriers can be detected by demonstrating nonrandom X-chromosome inactivation or the deleterious mutation in their T, B, or NK lymphocytes. Unless donor B or NK cells develop, patients with SCID have very poor B- and NK-cell function after nonablated bone marrow transplantation because of the many cytokine receptor defects, despite excellent reconstitution of T-cell function by donor-derived T cells.

AUTOSOMAL RECESSIVE SEVERE COMBINED IMMUNODEFICIENCY

This pattern of inheritance of SCID is less common in the United States than in Europe. Mutated genes on autosomal chromosomes have been identified in seven forms of SCID: ADA deficiency, Jak3 deficiency, IL-7 receptor a chain (IL-7Ra) deficiency, RAG1 or RAG2 deficiency, Artemis deficiency, and CD45 deficiency.

ADA Deficiency.

An absence of the enzyme adenosine deaminase (ADA) is observed in approximately 15% of patients with SCID, resulting from various point and deletional mutations in the ADA gene on chromosome 20q13-ter. Marked accumulations of adenosine, 2'-deoxyadenosine, and 2'-*C*-methyladenosine lead directly or indirectly to T-cell apoptosis, which causes the immunodeficiency. ADA-deficient patients usually have a much more profound lymphopenia than do infants with other types of SCID, with mean absolute lymphocyte counts of <500/mm^3 ; the absolute numbers of T, B and NK cells are very low. NK function is normal. After T-cell function is conferred by bone marrow

transplantation, without pretransplant chemotherapy, there is generally excellent B-cell function. This is because ADA deficiency affects primarily T-cell function. Milder forms of ADA deficiency have led to delayed diagnosis of immunodeficiency, even to adulthood. Other distinguishing features of ADA-deficient SCID include the presence of rib cage abnormalities similar to a rachitic rosary and numerous skeletal abnormalities of chondro-osseous dysplasia, which occur predominantly at the costochondral junctions, at the apophyses of the iliac bones, and in the vertebral bodies where a “bone-in-bone” effect is observed.

As with other types of SCID, ADA deficiency can be cured by HLA-identical or haploidentical T-cell-depleted bone marrow transplantation without the need for pre- or post-transplant chemotherapy; this remains the treatment of choice. Enzyme replacement therapy should not be initiated if bone marrow transplantation is possible because it confers graft-rejection capability. Gene therapy has been attempted several times over the last decade but until very recently had not been successful. A spontaneous in vivo reversion to normal of a mutation in the ADA gene has been reported.

Jak3 Deficiency.

Patients with this recently discovered autosomal recessive defect resemble all other types of SCID patients clinically. However, they have a lymphocyte phenotype similar only to that of patients with SCIDX1 with an elevated percentage of B cells and very low or no T and NK cells. Because Jak3 is the only signaling molecule known to be associated with $?_c$, it was a candidate gene for mutations leading to autosomal recessive SCID not attributable to ADA deficiency. Jak3 deficiency accounts for approximately 6% of SCID cases. Even after successful T-cell reconstitution by transplantation of haploidentical stem cells, patients with Jak3-deficient SCID fail to develop NK cells or normal B-cell function owing to the defective function of the many types of cytokine receptors that share $?_c$.

IL-7Ra Deficiency.

Patients with IL-7Ra-deficient SCID have a distinctive lymphocyte phenotype in that, though lacking T cells, they have normal or elevated numbers of both B and NK cells (T-, B+, NK+). This form of SCID represents approximately 10% of SCID cases in the United States. In contrast to patients with $?_c$ - and Jak3-deficient SCID, the immunologic defect in these patients is completely correctable even by T-cell–depleted haploidentical bone marrow stem cell transplantation.

RAG1 or RAG2 Deficiencies.

Infants with these causes of SCID have a different lymphocyte phenotype from those of patients with SCID due to $?_c$, Jak3, IL-7Ra, or ADA deficiencies in that they lack both B and T lymphocytes and have primarily NK cells in their circulation (T-, B-, NK+). This suggested a problem with their antigen receptor genes that led to the discovery of mutations in **recombinase activating genes, RAG1 or RAG2.** Such mutations result in a functional inability to form antigen receptors through genetic recombination.

Artemis Deficiency.

A very recently discovered cause of human SCID is a deficiency of a novel V(D)J recombination/DNA repair factor that belongs to the metallo-ß-lactamase superfamily, which is encoded on chromosome 10p by a gene called Artemis. Deficiency of this factor results in an inability to repair DNA after double-stranded cuts by the RAG1 or RAG2 gene products in rearranging antigen receptor genes from their germline configuration. Similar to RAG1 and RAG2 deficient SCID, this defect results in another form of T-, B-, NK+ SCID, also called **Athabascan SCID**. In addition, there is increased radiation sensitivity of both skin fibroblasts and bone marrow cells of those affected with this type of SCID.

CD45 Deficiency.

Another recently discovered molecular defect causing SCID is a mutation in the gene encoding the common leukocyte surface protein CD45. This hematopoietic cell–specific transmembrane protein tyrosine phosphatase functions to regulate src kinases required for T- and B-cell antigen receptor signal transduction. A 2-mo-old male infant presented with a clinical picture of SCID and was found to have a very low number of T cells but a normal number of B cells. The T cells failed to respond to mitogens, and serum immunoglobulins diminished with time. He was found to have a large deletion on one CD45 allele and a point mutation causing an alteration of the intervening sequence 13 donor splice site on the other allele. A second case of SCID due to CD45 deficiency has been reported.

RETICULAR DYSGENESIS

Reticular dysgenesis was first described in identical twin boys who exhibited a total lack of both lymphocytes and granulocytes in their peripheral blood and bone marrow. Seven of 8 infants with this defect died between 3 and 119 days of age as a result of overwhelming infections; 7 infants have been cured by bone marrow transplantation. The thymus glands have all weighed <1?g, have no Hassall corpuscles, and few or no thymocytes. Reticular dysgenesis is considered a variant of SCID. The molecular basis of this autosomal recessive disorder is unknown.

116.2 Combined Immunodeficiency (CID)

CID is distinguished from SCID by the presence of low but not absent T-cell function. Like SCID, however, CID is a syndrome of diverse genetic causes. Patients with CID have recurrent or chronic pulmonary infections, failure to thrive, oral or cutaneous candidiasis, chronic diarrhea, recurrent skin infections, gram-negative sepsis, urinary tract infections, and severe varicella in infancy. Although they usually survive longer than infants with SCID, they fail to thrive and die early in life. Neutropenia and eosinophilia are common. Serum immunoglobulins may be normal or elevated for all classes, but selective IgA deficiency, marked elevation of IgE, and elevated IgD levels occur in some cases. Although antibody-forming capacity is impaired in most

patients, it is not absent.

Studies of cellular immune function show lymphopenia, profound deficiencies of T cells, and extremely low but not absent lymphocyte proliferative responses to mitogens, antigens, and allogeneic cells in vitro. Peripheral lymphoid tissues demonstrate paracortical lymphocyte depletion. The thymus is very small with a paucity of thymocytes and usually no Hassall corpuscles. An autosomal recessive pattern of inheritance is common.

PURINE NUCLEOSIDE PHOSPHORYLASE DEFICIENCY

More than 40 patients with CID have been found to have purine nucleoside phosphorylase (PNP) deficiency. Point mutations identified in the PNP gene on chromosome 14q13.1 account for these deficiencies. In contrast to ADA deficiency, no characteristic physical or skeletal abnormalities have been noted, and serum and urinary uric acid are usually markedly deficient. Deaths result from generalized vaccinia, varicella, lymphosarcoma, or GVHD mediated by allogeneic T cells in nonirradiated blood or bone marrow. Two thirds of patients have neurologic abnormalities, and one third have autoimmune diseases. Lymphopenia is striking, primarily because of a marked deficiency of T cells; T-cell function is decreased to various degrees. The proportion of circulating NK cells is increased. Prenatal diagnosis is possible. Gene therapy is a possibility for the future, but thus far bone marrow transplantation has been the only successful form of therapy.

INTERLEUKIN 2 RECEPTOR a CHAIN (IL-2R a [CD25]) MUTATION

An infant boy born of a consanguineous union developed cytomegalovirus (CMV) pneumonia, persistent candidiasis, adenoviral gastroenteritis, failure to thrive, lymphadenopathy, hepatosplenomegaly, and chronic inflammation of his lungs and mandible. Biopsy specimens revealed extensive lymphocytic infiltration of his lung, liver, intestines, and bone. Serum IgA level was low. He had T-cell lymphopenia, and the T cells responded poorly to anti-CD3, phytohemagglutinin (PHA) and other mitogens, and IL-2. He was found to have a mutation in the gene encoding the IL-2 receptor a chain (IL-2Ra [CD25]), leading to truncation of the protein. He had no CD1 in his thymus, and an elevation of the anti-apoptotic protein *bcl*-2. This defect reveals that some components of cytokine receptors normally serve a negative regulatory role. Mutations in those components can result in unchecked lymphoproliferation and autoimmunity in addition to immunodeficiency.

CARTILAGE HAIR HYPOPLASIA

Cartilage hair hypoplasia (CHH) is an unusual form of short-limbed dwarfism with frequent and severe infections. It occurs predominantly among the Pennsylvania Amish, but non-Amish patients have been described.

Genetics and Pathogenesis.

CHH is an autosomal recessive condition. Numerous mutations that cosegregate with the CHH phenotype have been identified in the untranslated RNase MRP gene, which has recently been mapped to chromosome 9p21–p13 in Amish and Finnish families (see Table 116–1). The RNase MRP endoribonuclease consists of an RNA molecule bound to several proteins and has at least two functions: cleavage of RNA in mitochondrial DNA synthesis and nucleolar cleaving of pre-RNA. Mutations in RMRP cause CHH by disrupting a function of RNase MRP RNA that affects multiple organ systems. In vitro studies show decreased numbers of T cells and defective T-cell proliferation due to an intrinsic defect related to the G1 phase, resulting in a longer cell cycle for individual cells. However, NK cells are increased in number and function.

Clinical Manifestations.

Clinical features include short, pudgy hands; redundant skin; hyperextensible joints of hands and feet but an inability to extend the elbows completely; and fine, sparse, light hair and eyebrows. Severe and often fatal varicella infections, progressive vaccinia, and vaccine-associated poliomyelitis have been observed. Associated conditions include deficient erythrogenesis, Hirschsprung disease, and an increased risk of malignancies. The bones radiographically show scalloping and sclerotic or cystic changes in the metaphyses and flaring of the costochondral junctions of the ribs. Three patterns of immune dysfunction have emerged: defective antibody-mediated immunity, CID (most common), and SCID. The severity of the immunodeficiency varies; in one series, 11 of 77 patients died before age 20 yr but two were still alive at age 76. Bone marrow transplantation has resulted in immunologic reconstitution in some CHH patients with the SCID phenotype.

OMENN SYNDROME

Omenn syndrome is an autosomal recessive, fatal condition characterized by profound susceptibility to infection with T-cell infiltration of skin, intestines, liver, and spleen leading to an exfoliative erythroderma, lymphadenopathy, hepatosplenomegaly, and intractable diarrhea. Mutations in the recombinase activating genes, RAG1 and RAG2, have been found in several patients with this condition. Thus, this is a “leaky” form of SCID. These infants have persistent leukocytosis with marked eosinophilia and lymphocytosis; elevated serum IgE; low IgG, IgA, and IgM; low or absent B cells; and elevated numbers of clonal, likely autoreactive, T cells. There is dominance of TH2-like cells with severely impaired T-cell function due to the restricted heterogeneity of the host T-cell repertoire.

DEFECTIVE EXPRESSION OF MAJOR HISTOCOMPATIBILITY COMPLEX ANTIGENS

The two main forms of immunodeficiency and abnormalities of expression of the major histocopmatibility complex (MHC) are MHC class I (HLA-A, -B, and -C) antigen deficiency and MHC class II (HLA-DR, -DQ, and -DP) antigen deficiency. The associated defects of both B- and T-cell immunity and of HLA expression emphasize the important biologic role for HLA determinants in effective immune cell cooperation.

MHC Class I Antigen Deficiency

Isolated deficiency of MHC class I (HLA-A, -B, and -C) antigens, the **bare lymphocyte syndrome**, is rare. The resulting immunodeficiency is much milder than in SCID, contributing to a later age of presentation. Sera from affected children contain normal quantities of MHC class I antigens and $ß_2$ -microglobulin, but MHC class I antigens are not detected on any cells in the body. There is a deficiency of CD8 but not CD4 T cells. Mutations have been found in two genes within the MHC locus on chromosome 6 that encode the peptide transporter proteins, TAP1 and TAP2. TAP functions to transport antigenic peptides from the cytoplasm across the Golgi apparatus membrane to join the a chain of MHC class 1 antigens and $ß_2$ -microglobulin. All these are then assembled into a MHC class I complex that can then move to the cell surface. If the assembly of the complex cannot be completed because there is no antigenic peptide, the MHC class I complex is destroyed in the cytoplasm.

MHC Class II Antigen Deficiency

Many affected with MHC class II (HLA-DR, -DQ, and -DP) deficiency are of North African descent. Patients present in early infancy with persistent diarrhea that is often associated with cryptosporidiosis and enteroviral infections (e.g., poliovirus, coxsackievirus). They also have an increased frequency of infections with herpesviruses and other viruses, oral candidiasis, bacterial pneumonia, *P. carinii* pneumonia, and septicemia. The immunodeficiency is not as severe as in SCID, as evidenced by their failure to develop disseminated infection after BCG vaccination or GVHD from nonirradiated blood transfusions.

Four different molecular defects resulting in impaired expression of MHC class II antigens have been identified (see Table 116–1). One form is a mutation in the gene on chromosome 1q that encodes a protein called RFX5, a subunit of RFX, a multiprotein complex that binds the X box motif of MHC-II promoters. A second form is caused by mutations in a gene on chromosome 13q that encodes a second 36-kD subunit of the RFX complex, called RFX-associated protein (RFXAP). The most recently discovered and most common cause of MHC Class II defects are mutations in *RFXANK*, the gene encoding a third subunit of RFX. In a fourth type, there is a mutation in the gene on chromosome 16p13 that encodes a novel MHC class II transactivator (CIITA), a non–DNA-binding co-activator that controls the cell-type specificity and inducibility of MHC-II expression. All four of these defects cause impairment in the coordinate expression of MHC class II molecules on the surface of B cells and macrophages.

MHC class II–deficient patients have a very low number of CD4 T cells but normal or elevated numbers of CD8 T cells. Lymphopenia is only moderate. The MHC class II antigens HLA-DP, DQ, and DR are undetectable on blood B cells and monocytes, even though B cells are present in normal number.

Patients are hypogammaglobulinemic owing to impaired antigen-specific responses caused by the absence of these antigen-presenting molecules. In addition, MHC antigen-deficient B cells fail to stimulate allogeneic cells in mixed leukocyte culture. Lymphocyte proliferation studies show normal responses to mitogens but no response to antigens. The thymus and other lymphoid organs are severely hypoplastic, and the lack of class II molecules results in abnormal thymic selection with circulating CD4 T cells that have altered CDR3 profiles.

IMMUNODEFICIENCY WITH THROMBOCYTOPENIA AND ECZEMA (WISKOTT-ALDRICH SYNDROME)

Wiskott-Aldrich syndrome, an X-linked recessive syndrome, is characterized by atopic dermatitis, thrombocytopenic purpura with normal-appearing megakaryocytes but small defective platelets, and undue susceptibility to infection.

Genetics and Pathogenesis.

The abnormal gene, on the proximal arm of the X chromosome at Xp11.22–11.23 near the centromere, encodes a 501–amino acid proline-rich cytoplasmic protein restricted in its expression to lymphocytic and megakaryocytic cell lineages. This protein, now referred to as the **Wiskott-Aldrich syndrome protein (WASP)**, has been shown to bind CDC42H2 and *rac*, members of the Rho family of guanosine triphosphatases. WASP appears to control the assembly of actin filaments required for microvesicle formation downstream of protein kinase C and tyrosine kinase signaling. Carriers can be detected by nonrandom X-chromosome inactivation in several hematopoietic cell lineages or by demonstration of the deleterious mutation.

Clinical Manifestations.

Patients often have prolonged bleeding from the circumcision site or bloody diarrhea during infancy. The thrombocytopenia is not initially due to antiplatelet antibodies. Atopic dermatitis and recurrent infections usually develop during the 1st yr of life. *Streptococcus pneumoniae* and other bacteria having polysaccharide capsules cause otitis media, pneumonia, meningitis, and sepsis. Later, infections with agents such as *P. carinii* and the herpesviruses become more frequent. Survival beyond the teens is rare; infections, bleeding, and EBV-associated malignancies are major causes of death.

Patients with this defect uniformly have an impaired humoral immune response to polysaccharide antigens, as evidenced by absent or markedly diminished isohemagglutinins, and poor or absent antibody responses after immunization with polysaccharide vaccines. IgG2 subclass concentrations, surprisingly, are normal. Anamnestic responses to protein antigens are poor or absent. There is an accelerated rate of synthesis as well as hypercatabolism of albumin, IgG, IgA, and IgM, resulting in highly variable concentrations of different immunoglobulins, even within the same patient. The predominant immunoglobulin pattern is a low serum level of IgM, elevated IgA and IgE, and a normal or slightly low IgG concentration. Percentages of T cells are moderately reduced, and lymphocyte responses to mitogens are variably depressed.

ATAXIA-TELANGIECTASIA

Ataxia-telangiectasia is a complex syndrome with immunologic, neurologic, endocrinologic, hepatic, and cutaneous abnormalities.

Genetics and Pathogenesis.

The mutated gene responsible for this defect, **ataxia telangiectasia mutation (ATM)**, was mapped to the long arm of chromosome 11 (11q22–23) and has been cloned. The gene product is a DNA-dependent protein kinase localized predominantly to the nucleus and involved in mitogenic signal transduction, meiotic recombination, and cell cycle control. Cells from patients as well as those of heterozygous carriers have increased sensitivity to ionizing radiation, defective DNA repair, and frequent chromosomal abnormalities.

In vitro tests of lymphocyte function have generally shown moderately depressed proliferative responses to T- and B-cell mitogens. Percentages of CD3 and CD4 T cells are moderately reduced, with normal or increased percentages of CD8 and elevated numbers of Ti?/d T cells. Studies of immunoglobulin synthesis have shown both helper T-cell and intrinsic B-cell defects. The thymus is very hypoplastic, exhibits poor organization, and lacks Hassall corpuscles.

Clinical Manifestations.

The most prominent clinical features are progressive cerebellar ataxia, oculocutaneous telangiectasias, chronic sinopulmonary disease, a high incidence of malignancy, and variable humoral and cellular immunodeficiency. Ataxia typically becomes evident soon after these children begin to walk and progresses until they are confined to a wheelchair, usually by the age of 10–12 yr. The telangiectasias develop between 3 and 6 yr of age. The most frequent humoral immunologic abnormality is the selective absence of IgA, which is present in 50–80% of these patients. Hypercatabolism of IgA also occurs. IgE concentrations are usually low, and the IgM may be of the low molecular weight variety. IgG2 or total IgG levels may be decreased, and specific antibody titers may be decreased or normal. Recurrent sinopulmonary infections occur in approximately 80% of these patients. Although common viral infections have not usually resulted in untoward sequelae, fatal varicella has occurred. The malignancies associated with ataxia-telangiectasia are usually of the lymphoreticular type, but adenocarcinomas are also found. Unaffected relatives have an increased incidence of malignancy.

INTERFERON-? RECEPTOR 1 AND 2 AND IL-12 RECEPTOR ß1 MUTATIONS

Disseminated BCG infections occur in patients with severe T-cell defects, but no specific host defect is identified in approximately half of such cases. Explanations for this predilection have been discovered. The first was found in a 2.5-mo-old Tunisian girl who had fatal idiopathic disseminated BCG infection and in four children from Malta who had disseminated atypical mycobacterial infections in the absence of a recognized immunodeficiency. There was consanguinity in all, and each had a functional defect in the upregulation of tumor necrosis factor a (TNF-a) production by their blood macrophages in response to stimulation with interferon-? (IFN-?). Each was also found to have a mutation in the gene on chromosome 6q22–q23 that encodes the IFN-? receptor 1 (IFN-?R1). Patients with mutations in the IFN-?R2 have also been identified. A third type of defect was found in other patients who had disseminated mycobacterial infections and who were found to have mutations in the s1 chain of the IL-12 receptor (IL-12Rß1). IL-12 is a powerful inducer of IFN-? production by T and NK cells, and the mutated receptor chain gene resulted in unresponsiveness of these patients' cells to IL-12 and inadequate IFN-? production. Interestingly, the IFN-?R1, IFN-?R2, and IL-12Rß1-deficient children appeared not to be susceptible to infection with many agents other than mycobacteria. TH1 responses appeared to be normal in these patients. The susceptibility of these patients to mycobacterial infections thus apparently results from an intrinsic impairment of the IFN-? pathway response to these particular intracellular pathogens, showing that IFN-? is obligatory for efficient macrophage antimycobacterial activity.

HYPER IgE SYNDROME

The hyper IgE syndrome is a relatively rare primary immunodeficiency syndrome characterized by recurrent severe staphylococcal abscesses of the skin, lungs, and other viscera and markedly elevated levels of serum IgE. More than 200 patients with hyper IgE syndrome have been reported. The inheritance

pattern is as a single locus autosomal dominant trait with variable expression.

Clinical Manifestations.

These patients have histories from infancy of recurrent staphylococcal abscesses involving the skin, lungs, joints, and other sites. Persistent pneumatoceles develop as a result of recurrent pneumonias. The pruritic dermatitis that occurs is not typical atopic eczema, and it does not always persist. Allergic respiratory symptoms are usually absent. The first two reported patients were described as having **coarse facial features** including a prominent forehead, deep-set wide-spaced eyes, a broad nasal bridge, a wide fleshy nasal tip, mild prognathism, facial asymmetry, and hemihypertrophy. In older children, delay in shedding primary teeth, recurrent fractures, and scoliosis occur.

These patients demonstrate an exceptionally high serum IgE concentration; an elevated serum IgD concentration; usually normal concentrations of IgG, IgA, and IgM; pronounced blood and sputum eosinophilia; abnormally low anamnestic antibody responses; and poor antibody and cell-mediated responses to neoantigens. In vitro studies show normal percentages of blood T, B, and NK lymphocytes, with the exception of a decreased percentage of T cells with the memory (CD45RO) phenotype. Paradoxically, B cells from these patients demonstrate very low levels of IL-4–stimulated IgE synthesis in vitro, suggesting that they have already been maximally stimulated by a high level of endogenous IL-4. The molecular basis of this disorder remains unknown. Most patients have normal T-lymphocyte proliferative responses to mitogens but very low or absent responses to antigens or allogeneic

cells from family members. Blood, sputum, and histologic sections of lymph nodes, spleen, and lung cysts show striking eosinophilia. Hassall corpuscles and thymic architecture are normal. Phagocytic cell ingestion, metabolism and killing, and total hemolytic complement activity are normal in all patients. Results of chemotaxis studies have been mostly normal; thus, defective chemotaxis is not the basic problem in this syndrome.

The most effective therapy is long-term administration of therapeutic doses of a penicillinase-resistant anti-staphylococcal antibiotic, adding other agents as required for specific infections. Intravenous immunoglobulin (IVIG) should be administered to antibody-deficient patients, and appropriate thoracic surgery should be provided for superinfected pneumatoceles or those persisting beyond 6 mo.

116.3 Treatment of Cellular or Combined Immunodeficiency

Transplantation of MHC-compatible sibling or haploidentical (half-matched) parental bone marrow is currently the treatment of choice for patients with fatal T-cell or combined T- and B-cell defects. However, there is considerable optimism that gene therapy will be the treatment of choice for many of these defects in the future. The major risk to the recipient from transplants of bone marrow is that of GVHD. The development of techniques to deplete all post-thymic T cells from donor marrow permits safe and successful use of haploidentical related bone marrow stem cells for the correction of SCID and other fatal immunodeficiency syndromes. Patients with less severe forms of cellular immunodeficiency, including some forms of CID, Wiskott-Aldrich syndrome, cytokine deficiency, and MHC antigen deficiency, reject even HLA-identical marrow grafts unless chemoablative treatment is given before transplantation. Several patients with these conditions have been treated successfully with HLA-identical bone marrow transplantation after conditioning.

From 1968 to 1977, only 14 of 48 infants (29%) with SCID worldwide were long-term survivors after successful HLA class II–compatible bone marrow transplantation. The results of bone marrow transplantation have improved considerably during the past 25 years, possibly because of earlier diagnosis before untreatable opportunistic infections develop. A worldwide survey conducted by the author in 1997 revealed that 224 of 285 (79%) of patients with primary immunodeficiency transplanted with HLA-identical related marrow were surviving. Most encouraging are the results of T-cell–depleted haploidentical related marrow transplants in patients with primary immunodeficiency; 605 patients had had such transplants performed, and of those, 332 (55%) survive. The significance is even more impressive with the realization that most of the 605 recipients would have died had not the T-cell depletion techniques been developed. The greatest success has been in patients with SCID, who do not require pretransplant conditioning or GVHD prophylaxis; 100 of 128 (78%) patients with SCID transplanted by the author during the past 20 years survive, and all but 15 received T-cell–depleted parental marrow. Until somatic cell gene therapy is more fully developed, bone marrow transplantation remains the most important and effective therapy for these inborn errors of the immune system.

Section 3 - *The Phagocytic System*

Chapter 117 - Neutrophils

Laurence A. Boxer

The Phagocytic Inflammatory Response.

Neutrophils and mononuclear phagocytes share primary functions including the unusual ability to ingest large particles. Neutrophils are of only one type, but there are many varieties of mononuclear phagocytes including the tissue macrophages, and their circulating precursors, monocytes (Chapter 118). Neutrophils develop less rapidly in the bone marrow than monocytes, and remain for only 6 hours in the circulation (Table 117–1).

The hematopoietic progenitor system can be envisioned as a continuum of functional compartments with the most primitive compartment composed of very rare cells known as **pluripotential stem cells**, which have high self-renewal capacity. Pluripotential stem cells give rise to more mature stem cells, including cells that are committed to either lymphoid or myeloid development. Lymphoid stem cells give rise to T- and B-cell precursors and their mature progeny (Chapter 113). Trilineage myeloid stem cells, designated CFU-S for the spleen colony-forming unit described in mice, eventually give rise to committed single-lineage progenitors of the recognizable precursors through a random process of lineage restriction in a stepwise process (Fig. 117–1). The lineage restriction arises from cell-surface expression of lineage-specific growth factor receptors. Single-lineage progenitors, including erythroid burst-forming units (BFU-E), erythroid colony-forming units (CFU-E), megakaryocyte colony-forming units (CFU-Meg), and basophil, granulocyte, monocyte, and eosinophil colony-forming units (CFU-Baso, CFU-G, CFU-M, and CFU-Eo, respectively) proliferate and differentiate into their respective precursors in response to the growth factors that bind to their unique receptors. The capacity of lineage-specific committed progenitors to proliferate and differentiate in response to demand constitutes the most important buffer of the hematopoietic system against increased requirement for mature blood cell production.

TABLE 117-1 -- **Neutrophil and Monocyte Kinetics**

Neutrophils	
Average time in mitosis (myeloblast to myelocyte)	7–9 day
Average time in postmitosis and storage (metamyelocyte to neutrophil)	3–7 day
Average half-life in the circulation	6?hr
Average total body pool	6.5×10^{8} cells/kg
Average circulating pool	3.2×10^{8} cells/kg
Average marginating pool	3.3×10^{8} cells/kg
Average daily turnover rate	1.8×10^{10} cells/kg
Mononuclear Phagocytes	
Average time in mitosis	30–48?hr
Average half-life in the circulation	36–104?hr
Average circulating pool (monocytes)	1.8×10^{7} cells/kg
Average daily turnover rate	1.8×10^{9} cells/kg
Average survival in tissues (macrophages)	Mo

Hematopoietic Growth Factors.

The proliferation, differentiation, and survival of immature hematopoietic progenitor

cells are governed by **hematopoietic growth factors (HGFs)**, a family of glycoproteins (Table 117–2). Besides regulating proliferation and differentiation of progenitors, these factors influence the survival and function of mature blood cells. The HGFs include the **interleukins** and the **colony-stimulating factors (CSFs)**, which have been named for their ability to stimulate progenitor cells to form colonies of recognizable mature cells in vitro. The majority of lineage-specific progenitors require the presence of additional growth factors such as interleukin 3 (IL-3) or granulocyte-macrophage CSF (GM-CSF) in addition to a lineage-specific HGF to generate the colonies for which they are programmed. Hence, immature committed progenitors bear receptors for IL-3, stem cell factor (SCF), GM-CSF, and IL-6 (Fig. 117–2). These committed progenitors differ from one another with respect to their lineage-specific receptors; this allows the lineage-specific HGF to produce the colonies for which they are programmed. During granulopoiesis and monopoiesis, several cytokines regulate progenitor cells or mature effector cells at each stage of maturation and differentiation from the primitive pluripotent stem cells to nondividing terminally differentiated cells (monocytes, neutrophils, eosinophils, and basophils). The actions of these growth factors are mediated through lineage-specific receptors. As cells mature, they lose receptors for most cytokines, especially those that influence early cell development, such as SCF. Once the cells have matured, however, they express receptors for chemokines, which help direct the cells to sites of inflammation.

Neutrophil Maturation and Kinetics.

The bone marrow microenvironment supporting the progenitors and precursors must provide for the normal steady-state rates of renewal of the cellular elements of blood through its ability to provide growth and differentiation factors generated by stromal cells themselves. The growth factors such as granulocyte colony-stimulating factor (G-CSF) and GM-CSF not only stimulate cell division, but also affect the synthesis of many cytoplasmic components of the neutrophil as well as expression of transcription factors that are necessary for myeloid cell differentiation. Transcription factors such as PU.1, Sp-1, C/EBP alpha, and Oct-1 affect myeloid differentiation. For example, the promoter for the myeloblastin gene has a binding site for PU.1, which is engaged following activation of myeloid progenitor cells with G-CSF. Normally, the production rates precisely equal destruction rates. Granulocytes survive intravascularly for only 6–12?hr and therefore daily production of 2×10^4 granulocytes/µL of blood is required to maintain a level of circulating granulocytes of 5×10^3 /µL. In contrast, lymphocytes that can exhibit lifetimes measured in months or years require daily renewal of certain lymphocyte progenitors at rates substantially lower than the other hematopoietic progenitors.

The process of intramedullary granulocyte maturation involves changes in nuclear configuration and accumulation of specific intracytoplasmic granules (see Table 117–2). The relatively small peripheral blood pool is compartmentalized into the **circulating pool** and the **marginating pool**. The peripheral blood pool provides entrance into the tissue and is buffered by an immense marrow reserve of identifiable precursors, some of which are undergoing mitosis and some of which are maturing into bands and neutrophils. Proliferation of myeloid cells

Figure 117-1 Major cytokine sources and actions. Cells of the bone marrow microenvironment such as macrophages (ma), endothelial cells (ec), and reticular fibroblastoid cells (fb) produce macrophage colony-stimulating factor (M-CSF), granulocytemacrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), interleukin (IL-6), and probably stem cell factor (SCF; cellular sources not yet precisely determined) after induction with endotoxin (ma) or IL-1/TNF (ec, fb). T cells produce IL-3, GM-CSF, and IL-5 in response to antigenic and IL-1 stimulation. These cytokines have overlapping actions during hematopoietic differentiation, as indicated, and for all lineages optimal development requires a combination of early- and late-acting factors. PSC = pluripotent stem cells; MSC = myeloid stem cells; TNF = tumor necrosis factor. (Modified from Sieff CA, Nathan DG, Clark SC: The anatomy and physiology of hematopoiesis. In Nathan DG and Orkin SH [editors]: *Hematology of Infancy and Childhooa*, 5th ed. Philadelphia, WB Saunders, 1997.)

consisting of approximately five divisions takes place only during the first three stages of neutrophil development (myeloblast, promyelocyte, and myelocyte). After the myelocyte stage, the cells terminally differentiate into metamyelocytes, bands, and neutrophils. Neutrophil maturation is associated with changes in the nucleus and with the production of azurophilic primary granules and specific or secondary granules. A myeloblast is a relatively undifferentiated cell with a large oval nucleus, a sizeable nucleolus, and a deficiency of granules. Promyelocytes acquire peroxidase-positive

TABLE 117-2 -- Major Human Hematopoietic Growth Factors and Cytokines

Factor	Synonym	Source	Biologic Activities	
			Progenitors	*Mature Cells*
SCF	Steel factor Stem cell factor Kit ligand	Stromal fibroblasts Vascular endothelium	Synergistic with IL-3, IL-11, IL-6 on blast CFC Synergistic with IL-3, GM-CSF, G-CSF, erythropoietin, thrombopoietin on committed CFC	Mast cell & stem cell growth
Flt, ligand		Spleen	Synergistic with SCF, IL-3, IL-11 on blast CFC	
		Lung	Synergistic with IL-3, GM-CSF, G-CSF on committed CFC	

			Synergistic with IL-7, SCF on B-cell progenitors	
IL-3	Multi CSF	T cells	All CFC	Eosinophils
		Mast cells		B cells
				Monocytes
GM-CSF	CSFa	T cells	All CFC	Neutrophils
		Endothelium		Monocytes
		Fibroblasts		Eosinophils
		Monocytes		
G-CSF	CSFß	Monocytes	CFU-granulocyte	Neutrophils
		Endothelium		
		Fibroblasts		
IL-5		T cells	CFU-eosinophil	Eosinophils
		Mast cells		
M-CSF	CSF-1	Fibroblasts	CFU-monocyte	Monocytes
		Endothelial cells		
Erythropoietin		Kidney	BFU-erythroid, CFU-erythroid	Erythroblasts
Thrombopoietin		Liver	CFU-megakaryocyte	Megakaryocytes
		Kidney		
		Fibroblasts		
		Endothelium		
IL-1a		Monocytes	Synergistic with SCF, IL-3 on blast CFU	Activates cytokine production
		Fibroblasts		
		Endothelium		
IL-1ß		Monocytes		
		Fibroblasts		
		Endothelium		
		Kupffer cells		
		Smooth muscle		
IL-2		T cells	T cell growth factor	Activates B cells and NK cells

IL-4		T cells	Promotes B cell differentiation and dendritic cell proliferation & differentiation	IgG induction factor
		Mast cells		
IL-6		Monocytes	Synergistic: SCF, IL-3, on blast CFU	
		T cells		
		B cells		
		Fibroblasts		
		Endothelium		
		Kupffer cells		
IL-7		Stromal cells	Growth factor for B & T cells	
IL-9		TH2 cells	Mast cell growth	
			Synergistic with Epo on BFU	
IL-10		T helper and B cells, keratinocytes, macrophages	Mast cell and B cell proliferation	B cell antibody production suppresser, cytokine production from monocyte and T-helper cells
IL-11		Stromal fibroblasts	Synergistic with SCF, IL-3 on blast CFC	Megakaryocytes
			Synergistic with IL-3, SCF on CFU-megakaryocyte	
IL-12		Macrophages		Induces IFN-? and cell-mediated immunity from T cells and NK cells
		B cells		
IL-13		T cells	Growth and proliferation of T cells	Promotes IgE production from B cells
IL-14		T cells, some B cell malignancies		Inhibits Ig synthesis

IL-15		Monocytes, neutrophils, fibroblasts	Growth and proliferation of T cells	
IL-16		Activated T helper and T suppressor cells		Activates T helper cells
		Eosinophils		
		Mast cells		
IL-17		T helper and T suppressor		Activates macrophages to secrete cytokines
IL-18		Stromal cells		Induces IFN?secretion from T helper cells & NK cells
		Macrophages		
IFNa,ß		Leukocytes, fibroblasts	Antiproliferative for CFU-GM and BFU-E	Immune modulator of NK cells and monocytes
IFN?		T cells, NK cells	Antiproliferative like CFU-UM and BFU-E	Immune-modulating and induces cell membrane antigens (MHC class I or II)
TNF a, ß		Macrophages, somatic cells, T & B lymphocytes		Immunoenhancing & induces apoptosis of many cells; induces secondary production of cytokines by stromal cells
MIP-1a		T & B cells	Inhibits growth of hematopoietic progenitors	
		Neutrophils		
		Macrophages		

SCF = stem cell factor; CFC = colony-forming cell; CFU = colony-forming unit; BFU-E = erythroid burst-forming unit; IL = interleukin; GM-CSF = granulocyte-macrophage colony-stimulating factor; G-CSF = granulocyte colony-stimulating factor; M-CSF = monocyte colony-stimulating factor; TNF = tumor necrosis factor; IFN = interferon; NK = natural killer.

Figure 117-2 Various cytokines and chemokines that act at different levels of granulopoiesis and monocytopoiesis. Multiple cytokines regulate progenitor cells or mature effector cells at each stage of maturation/differentiation from the primitive pluripotent stem cell to nondividing terminally differentiated precursors (monocytes, neutrophils, eosinophils, and basophil/mast cells). The cytokines and chemokines also have varying degrees of specificity; some, such as M-CSF and IL-5, act predominantly on the monocytic and eosinophilic pathways, respectively, whereas others, such as CSF-GM, act on multiple granulocytic-monocytic (erythroid not shown) cell types. (Modified from Abboud CN, Liesveld JL: Granulopoiesis and monocytopoiesis. In Hoffman R, Benz EB, Shattil SJ, et al [editors]: *Hematology: Basic Principles and Practice*, 2nd ed. New York, Churchill Livingstone, 1995.)

azurophilic granules, and myelocytes acquire specific granules. Chromatin condensation, loss of nucleoli, and the shape changes of the nucleus result in the morphometric characteristic of the segmented neutrophil.

Neutrophil Function.

Neutrophil responses are initiated as circulating neutrophils flowing through the postcapillary venules detect low levels of chemokines and other chemotactic substances released from a site of infection. These soluble effectors of inflammation trigger subtle changes in the array and activity of surface molecules on both endothelial cells and neutrophils. The initial associations are low affinity, reversible, and mediated primarily by cell-selectin-carbohydrate interactions. This leads to the phenomenon known as leukocyte rolling, in which loose adhesions are made and broken, causing neutrophils to move hesitantly along the endothelial surface. The rolling of neutrophils allows more intense exposure of neutrophils to activating factors such as tumor necrosis factor (TNF) or IL-1 (Fig. 117–3). This leads to induction of qualitative and quantitative changes in the family of ß2 integrin adhesion receptors on the neutrophils (the CD11/CD18 group of surface molecules). The activated integrin receptors mediate tight heterotypic adhesion between neutrophils and endothelial cells and hemotypic adhesion of neutrophils with each other. The net result of these interdependent intercellular interactions is that neutrophils flatten onto the endothelial cells, while neutrophil/neutrophil and neutrophil/platelet aggregates partially occlude the venule and reduce blood flow.

The next phase involves loosening of the integrin adhesion through the process of mobilizing integrin receptors to the trailing pseudopod of the neutrophil. The neutrophil is able to displace its integrin receptors and undergo conformational changes allowing it to migrate between endothelial cell junctions into the extravascular tissue. Once through the endothelium, the neutrophil senses the gradient of chemokines or other chemoattractants and migrates to sites of infection. Neutrophil migration is a complex process involving rounds of receptor engagement, signal transduction, and remodeling of the actin-microfilaments composing in part the cytoskeleton. Additionally, secretion of specific granules or related secretory vesicular elements containing gelatinase, heparinase, and other enzymes allows the neutrophil to cross the basement membrane and transit through connective tissues. When the neutrophil reaches the site of infection, it recognizes pathogens by means of Fc immunoglobulin and complement receptors, fibronectin receptors, and other

adhesion molecules.

The neutrophil ingests microbes that are opsonized (prepared for ingestion) by heat-soluble and heat-labeled factors in human

Figure 117-3 The neutrophil-mediated inflammatory response. *A*, Unstimulated neutrophils (expressing L-selectin) entering a post capillary venule. *B*, Invasion of gram-negative bacteria with release of lipopolysaccharide stimulates tissue macrophages to secrete inflammatory monokines, IL-1 and TNF, which, in turn, activate endothelial cells to express E- and P-selectins. E- and P-selectins serve as counter receptors for neutrophils sialyl Lewis X and Lewis X to cause low-avidity neutrophil rolling. *C*, Activated endothelial cells express ICAM-1, which serves as a counter-receptor for neutrophil $ß_2$ integrin molecules, leading to high-avidity leukocyte spreading and the start of transendothelial migration. Transendothelial migration of activated neutrophils is stimulated by chemotactic factors such as endothelial cell-derived IL-8 and formylated bacterial factors. Chemoattractants promote neutrophil activation with release of L-selectin and an increase in $ß_2$ integrin affinity for ICAM-1 and for other counter-receptors promoting intravascular and neutrophil aggregation. *D*, Neutrophils invade through the vascular basement membrane with the release of proteases and reactive oxidative intermediates, causing local destruction of surrounding tissue at sites of high concentrations of chemotactic factors. (From Smolen JE, Boxer LA: Functions of neutrophils. In Williams WJ, Beutler E, Erslev AJ, et al [editors]: *Hematology*, 5th ed. New York, McGraw-Hill, 1994, with permission of The McGraw-Hill Companies.)

serum, which include immunoglobulin G (IgG) and C3, respectively. These opsonins facilitate phagocytosis of microbes, in which the pathogens are engulfed into a closed vacuole called a **phagosome** (Fig. 117–4).

As phagocytosis proceeds, two cellular responses essential for optimal microbicidal activity occur concomitantly, **degranulation** and activation of **nicotinamide-adenine dinucleotide phosphate (NADPH)–dependent oxidase**. Fusion of neutrophil granule membranes with the phagosome membrane occurs, resulting in the delivery of potent antimicrobial proteins into the phagosome. In coordinated succession, the contents of the specific granules and then contents of the azurophil granules are secreted into the phagosome. Occurring concomitantly are assembly and activation of NADPH oxidase at the phagosome membrane (Fig. 117–5). This enzyme generates large amounts of superoxide (O_2^-) from molecular oxygen that in turn decomposes to produce hydrogen peroxide (H_2O_2) and singlet oxygen. H_2O_2 can react with O_2^- to form hydroxyl radicals. In the presence of myeloperoxidase (a major azurophil granule component), a reaction is catalyzed and uses H_2O_2 and ubiquitously present chloride ion to create hypochlorous acid (HOCl) in the phagosome. Although H_2O_2 and HOCl are microbicidal, evidence shows that these agents modulate host defense. First, these oxidants can denature proteins, making them more susceptible to proteolysis. Additionally, some of the neutrophil proteases are activated by the oxidants. These events jointly serve to enhance breakdown or clearance of pathogens from the site of infection. Also, the oxidants can inactivate chemotactic factors and may serve to terminate the process of neutrophil influx, thereby attenuating the inflammatory process.

Figure 117-4 The mechanisms for the production, action, and detoxification of peroxides in neutrophils. Oxygen is reduced to superoxide (O^-_2) by an oxidase. NADPH is regenerated from NADPH by the hexose monophosphate shunt. Superoxide may spontaneously decompose to hydrogen peroxide in singlet oxygen ($^1O_2$). Hydrogen peroxide can react with superoxide to form hydroxyl radicals and generate bactericidal aldehydes (RCHO) by oxidizing bacterial constituents in the presence of halide ions and myeloperoxidase that were delivered to the phagosome by degranulation. Hydroxyl radicals (•OH) can peroxidize unsaturated fatty acids of the phagosomal membrane and thus yield the potentially bactericidal aldehydes. Hydrogen peroxide in the presence of myeloperoxidase and chloride ion can create hypochlorous acid (HOCl) in the phagosome. Superoxide leaking out of the phagosome may be converted rapidly to hydrogen peroxide by superoxide dismutase (SOD). Hydrogen peroxide in the cytosol is destroyed by catalase or reduced glutathione (GSH). Glutathione is regenerated by coupled reactions that stimulate the flow of glucose-6-phosphate (G-6-P) into the hexose monophosphate shunt. (Modified from Stossel TP, Boxer LA: Functions of neutrophils. In Williams WJ, Beutler E, Erslev AJ, Lichtman MA [editors]: *Hematology*, 3rd ed. New York, McGraw-Hill, 1972, p 751.)

Figure 117-5 This is a modification of a hypothetical model of NADPH oxidase activation. Current knowledge suggests that the oxidase in its dormant state *(left)* is composed of both membrane-bound and cytosolic components. The former includes the $gp91^{phox}$ and $p22^{phox}$ subunits of cytochrome-b (and possibly Rap-1A). The flavin and heme groups (Fe) that mediate the transfer of electrons from NADPH to molecular oxygen are localized in the cytochrome. The cytosolic components $p47^{phox}$ and $p67^{phox}$ may exist as a preformed complex of 260?kD, which includes a third protein, $p40^{phox}$. The small GTPase Rac2 is present in the cytosol in its inactive guanosine diphosphate-bound state (GDP). Following phagocyte activation, the cytosolic complex translocates to the membrane, which may be under the control of the active guanosine triphosphate (GTP)–bound form of Rac2 and further regulated by phosphorylation of $p47^{phox}$. By a mechanism that is not fully understood, binding of the cytosolic components activates the flavocytochrome to catalyze the transfer of electrons from NADPH to oxygen through the FAD and heme redox centers. (Modified from Curnutte J, Orkin S, Dinauer M: Genetic disorders of phagocyte function. In Stamatopyannopoulous G, Nienhuis AW, Majerus PW, Varmus H [editors]: *The Molecular Basis of Blood Diseases*, 2nd ed. Philadelphia, WB Saunders, 1994, p 522.)

Chapter 118 - Monocytes and Macrophages

Richard B. Johnston Jr.

Mononuclear phagocytes (monocytes and macrophages) have a central and essential role in the immune response, in host defense against infection, and in tissue repair and remodeling. No human has been identified as having congenital absence of this cell line, probably because macrophages are required to remove primitive tissues during fetal development as new tissues develop to replace them. Monocytes and tissue macrophages in their various forms (Box 118–1) constitute the **mononuclear phagocyte system**. These cells are a system because of their common origin, similar morphology, and common functions, particularly efficient phagocytosis.

Development.

Monocytes, the circulating precursors of tissue macrophages, develop more rapidly in the bone marrow and remain longer in the circulation than do neutrophils (see Table 117–1). The first recognizable monocyte precursor is the monoblast, followed by the promonocyte, a somewhat larger cell with cytoplasmic granules and an indented nucleus containing finely divided chromatin, and finally the fully developed monocyte. A mature monocyte is larger than a neutrophil and has a cytoplasm filled with granules whose contents include hydrolytic enzymes. The transition from monoblast to mature circulating monocyte requires about 6 days. Monocytes retain a limited capacity to divide, and they undergo considerable further differentiation after entering the tissues, where they may live for weeks to months.

Migration of monocytes into the different tissues appears to occur randomly in the absence of localized inflammation. Once in the tissues, monocytes undergo transformation into tissue macrophages with morphologic and sometimes functional properties that are characteristic for the tissue in which they reside (see Box 118–1). Organ-specific factors influence monocyte differentiation and endow each tissue macrophage with particular metabolic and structural features. Monocytes in the liver become **Kupffer cells** that bridge the sinusoids separating adjacent plates of hepatocytes. Those at the lung airway surface become large ellipsoid **alveolar macrophages**, and those in the bone become **osteoclasts**. All macrophages have at least three major functions in common: presentation of antigens, phagocytosis, and immunomodulation through release of a variety of potent factors broadly termed cytokines. At sites of

Granuloma (multinucleated giant cells)

inflammation, monocytes and macrophages can fuse to form multinucleated giant cells, the terminal stage of development in the mononuclear phagocyte line. Blood monocytes, when exposed to certain cytokines, can differentiate into **dendritic cells**, which are especially effective at presenting antigen to lymphocytes.

Activation.

The most important step in the functional maturation of macrophages is the conversion from a resting to an activated macrophage. Activation is driven primarily by certain cytokines, proteins that mediate signaling between cells and thereby influence inflammation or the immune response. **Cytokines** include interferons, interleukins, growth factors, chemokines, and tumor necrosis factors. Cytokines responsible for macrophage activation include interferon-? (IFN-?); granulocyte-macrophage colony-stimulating factor (GM-CSF); macrophage-CSF; and tumor necrosis factor–a (TNF-a). Growth hormone and bacterial endotoxin or cell wall proteins also can induce activation. In its most widely accepted sense, the term **activated macrophage** indicates that the cell has an enhanced capacity to kill microorganisms or tumor cells. Activated macrophages are larger, with more pseudopods and pronounced ruffling of the plasma membrane, and they exhibit accelerated activity of many functions (Box 118–2).

Macrophage activation is accomplished during infection through the engagement of CD40 on macrophages with CD40 ligand on antigen-sensitized helper T lymphocytes and through cytokines from these T cells. Activated macrophages and macrophages encountering microorganisms release interleukin (IL)-12, which, in turn, activates the T cells. These interactions constitute the basis of cell-mediated immunity. IFN-? is an especially important macrophage-activating cytokine that is currently used for preventing infection in patients with chronic granulomatous disease and for treating the decreased bone resorption of congenital osteopetrosis, which is caused by decreased function of osteoclasts.

Macrophages exposed to endotoxin or other inflammatory mediators release TNF-a, which itself can activate other macrophages. As macrophages become activated, they express greater numbers of receptors for TNF-a. Thus, macrophages at sites of inflammation have the potential to activate themselves and thereby achieve enhanced function more rapidly than through the classic cell-mediated immune response, which

requires accumulation of a population of sensitized T lymphocytes. Conversely, macrophages, as well as helper T cells, secrete IL-10, which inhibits the production of IFN-? and serves to suppress the potentially damaging effects of uncontrolled macrophage activation.

Functional Activities.

Numerous functions are upregulated when the macrophage is activated (see Box 118–2). Obviously important are the ingestion and killing of such intracellular pathogens as *Mycobacterium tuberculosis, Listeria, Leishmania, Toxoplasma*, and some fungi, but macrophages also clear from the bloodstream and eliminate such extracellular pathogens as *Streptococcus pneumoniae*. Killing of the ingested organisms depends heavily on products of the respiratory burst (e.g., hydrogen peroxide) and on nitric oxide; release of these toxic metabolites is enhanced in activated macrophages.

The activity of mononuclear phagocytes against cancers in humans is less well understood. This activity may not involve the phagocytic process. Rather, macrophages may kill tumor cells by means of secreted products including lysosomal enzymes, nitric oxide, oxygen metabolites, cytolytic proteinases, and TNF-a. Proteolytic enzymes and cytocidal factors present on the surface membrane of monocytes may have a role in tumor rejection.

Essential to the monocyte's protective function is its capacity to undergo diapedesis across the endothelial wall of blood vessels and to migrate to sites of microbial invasion in tissues. Chemotactic factors for monocytes include complement products and chemoattractants (chemokines) derived from neutrophils, lymphocytes, and other cell types. Phagocytosis of the invading organisms or cells can then occur, influenced by the presence or absence of opsonins (antibody, complement, mannose-binding and surfactant proteins) for the invader, the inherent surface properties of the microorganism or tumor, and the state of activation of the macrophage.

Other important functions of macrophages are disposal of damaged and dying cells, which helps resolve the immune response, and wound healing. Macrophages lining the sinusoids of the spleen are particularly important in ingesting aged erythrocytes. Macrophages in inflammatory sites can recognize changes in phosphatidylserine on the membrane of lymphocytes and neutrophils undergoing programmed cell death, and these can be removed before they become necrotic and spill their toxic contents into the tissue. Macrophages are phylogenetically primitive and can be identified early in fetal development, where they function to remove debris as one maturing embryonic tissue replaces another. They are also important in removing inorganic particles, such as elements of cigarette smoke or dust that enter the alveoli.

Macrophages are integrally involved in the induction and expression of specific immune responses, including antibody formation and cell-mediated immunity. This involvement depends on their capacity to break down foreign material in phagocytic and pinocytic vesicles and then present individual antigens on their surface as peptides or polysaccharides bound to class II major histocompatibility complex (MHC) molecules. B lymphocytes and, especially, dendritic cells can also present antigen and serve as “accessory cells” for the specific immune response. Expression of MHC class II molecules is increased in activated macrophages, and antigen presentation is more effective.

The heightened capacity of activated macrophages to synthesize and release various hydrolytic enzymes and potentially microbicidal materials (see Box 118–2) probably plays a part in their increased killing capacity, although not every macrophage product is secreted in increased amounts when the cell is activated. The macrophage is an extraordinarily active secretory cell; approximately 100 distinct substances have been identified as being secreted by it, placing this cell in a class with the hepatocyte. Because of the profound effect of some of these secretory products on other cells, the large number of macrophages, and their widespread distribution, the mononuclear phagocyte system can be viewed as an important endocrine organ. IL-1 illustrates this point well. Microbes and microbial products, burns, ischemia-reperfusion, and other causes of inflammation or tissue damage stimulate the release of IL-1, mainly by monocytes and macrophages. In turn, IL-1 elicits fever, sleep, and release of IL-6, which induces production of acute phase proteins.

Abnormalities of Monocyte-Macrophage Function.

Mononuclear phagocytes, as well as neutrophils, from patients with chronic granulomatous disease exhibit a profound defect of phagocytic killing (Chapter 120). The inability of affected macrophages to kill ingested organisms leads to abscess formation and characteristic granulomas at sites of macrophage accumulation in the liver, lungs, spleen, and lymph nodes. Genetic deficiency of the CD11/CD18 complex of membrane adherence glycoproteins (leukocyte adhesion defect), which includes a

receptor for opsonic complement component 3, results in impaired phagocytosis by monocytes (Chapter 120).

The monocyte-macrophage system is prominently involved in several lipid storage diseases (sphingolipidoses; Chapter 75.3). In these conditions, the expression in macrophages of a systemic enzymatic defect permits the accumulation of cell debris that is normally cleared by macrophages. Resistance to infection can be impaired, at least partly because of impairment in macrophage function. Gaucher disease is the prototype for these disorders. In this condition, the enzyme glucocerebrosidase functions abnormally, thus allowing accumulation of glucosylceramide (glucocerebroside) from cell membranes in Gaucher cells throughout the body. In all locations, the Gaucher cell is an altered macrophage. These patients can be treated with infusions of the normal enzyme modified to expose mannose residues, which bind to mannose receptors on macrophages.

The cytokine IL-12 is a powerful inducer of IFN-? production by T cells and natural killer cells. Individuals with inherited deficiency in macrophage receptors for IFN-? or lymphocyte receptors for IL-12, or in IL-12 itself, suffer a severe, profound, and selective susceptibility to infection by nontuberculous mycobacteria such as *Mycobacterium avium* or bacillus Calmette-Guérin (BCG). About half of these patients have had disseminated *Salmonella* infection. These abnormalities are now grouped under the term **leukocyte mycobactericidal defects**.

Monocyte-macrophage function has been shown to be abnormal in various other clinical conditions. In most of these, however, the abnormality is partial and only a suspected cause of increased infection. For example, cultured mononuclear phagocytes of newborns are more readily infected than adult cells by human immunodeficiency virus (HIV)–1 and measles virus. Macrophages from newborns release less G-CSF and IL-6 in culture, and this deficiency is accentuated in cells from preterm infants. This finding supports the observations that levels of G-CSF are significantly decreased in blood from term and preterm infants, and that the bone marrow granulocyte storage pool is diminished in infants, particularly those born before term. Macrophages from newborns are poorly activated by IFN-?, which could weaken resistance to infection by intracellular pathogens.

The term **histiocyte** was originally used to describe cells thought to be macrophages in fixed tissue preparations. It is now clear that histiocytosis X represents a malignancy-like overgrowth of Langerhans-type dendritic cells (Chapter 499). Thus, the term **Langerhans cell histiocytoses** better describes these disorders because histiocyte is a histologic term and not cell specific.

Chapter 119 - Eosinophils

Laurence A. Boxer

Eosinophils are distinguished from other leukocytes by their morphology, constituent products, and association with specific diseases. Eosinophils are nondividing fully differentiated cells with a diameter of approximately 8?µm and a bilobed nucleus. They differentiate from stem cell precursors in the bone marrow under the control of T cell–derived interleukin 3 (IL-3), granulocyte-macrophage colony-stimulating factor (GM-CSF), and especially IL-5. Their characteristic membrane-bound specific granules stain reddish brown with eosin and consist of a crystalline core made up of major basic protein (MBP) surrounded by matrix containing the eosinophil cationic protein (ECP), eosinophil peroxidase (EPO), and eosinophil-derived neurotoxin (EDN). These basic proteins are cytotoxic for the larval stages of helminthic parasites such as *Schistosoma mansoni*, and are also thought to contribute to much of the inflammation associated with asthma, causing sloughing of epithelial cells and contributing to clinical dysfunction (Chapter 134). Both eosinophil MBP and ECP are also present in large quantities in the airways of patients who have died of asthma and are thought to inflict epithelial cell damage that contributes to airway hyperresponsiveness. MBP has the potential to activate other proinflammatory cells including mast cells, basophils, neutrophils, and platelets. Eosinophils have the capacity to generate large amounts of the lipid mediators, platelet-activating factor (PAF) and leukotriene-C4, both of which can cause vasoconstriction and mucus hypersecretion. Eosinophils are a source of a number of proinflammatory cytokines including IL-1, IL-3, IL-5, and GM-CSF. Thus, eosinophils have a potent armory of mediators whose potential to initiate and sustain an inflammatory response is considerable.

Eosinophil migration from the vasculature into the extracellular tissue is mediated by the binding of leukocyte adhesion receptors to their ligands or counterstructures on the postcapillary endothelium. Similar to neutrophils, transmigration begins as the eosinophil selectin receptor binds to the endothelial carbohydrate ligand in loose association, which promotes eosinophils rolling along the endothelial surface until they encounter a priming stimulus such as a chemotactic mediator. Eosinophils then establish a high-affinity bond between integrin receptors and their corresponding immunoglobulin-like ligand. Unlike neutrophils, which become flattened before transmigrating between the tight junctions of the endothelial cells, eosinophils can use unique integrins, known as VLA-4, to bind to vascular cell adhesion molecule (VCAM)–1, which enhances eosinophil adhesion and transmigration through endothelium. Eosinophils are recruited to tissues in inflammatory states by the chemokine, **eotaxin**. These unique pathways account for selective accumulation of eosinophils in allergic and inflammatory disorders. Eosinophils normally dwell primarily in tissues, especially tissues with an epithelial interface with the environment, including the respiratory, gastrointestinal, and lower genitourinary tracts. The life span of eosinophils may extend for weeks within tissues.

In addition to selectively enhancing eosinophil production as well as adhesion to endothelial cells, IL-5 also has a number of important effects on eosinophil function. Considerable evidence shows that IL-5 has a pivotal role in promoting eosinophil accumulation. It is the predominant cytokine in allergen-induced pulmonary late-phase reaction, and antibodies against IL-5 block eosinophil infiltration into the lungs in animal models associated with airway hyperresponsiveness following allergen challenge. Eosinophils also bear unique receptors for several chemokines. These include RANTES, eotaxin, monocyte chemotactic protein (MCP)–3, and MCP-4. These chemokines appear to be key mediators in the induction of tissue eosinophilia.

Blood eosinophil numbers do not always reflect the extent of eosinophil involvement in disease-affected tissues. The **absolute eosinophil count**, calculated as the white blood cell (WBC) count/µL × per cent of eosinophils, is usually less than 450 cells/µL in the blood and varies diurnally, being more abundant in the early morning and diminishing as endogenous glucocorticoid levels rise. Eosinopenia occurs after corticosteroid administration and with some bacterial and viral infections.

DISEASES ASSOCIATED WITH EOSINOPHILIA

Many diseases are associated with eosinophilia (Box 119–1). The genesis of sustained eosinophilia in some patients remains unclear. Patients with sustained blood eosinophilia may develop organ damage, especially cardiac damage as found in the idiopathic hypereosinophilic syndrome, and should be monitored for evidence of cardiac disease.

Allergic Diseases.

Allergy is the most common cause of eosinophilia in children in the United States. Acute allergic reactions may cause eosinophilic leukemoid responses with absolute eosinophil counts exceeding 20,000 cells/µL; chronic allergy is rarely associated with absolute eosinophil counts of more than 2,000 cells/µL. Hypersensitivity drug reactions can elicit eosinophilia that is often not accompanied by drug fever or organ dysfunction. Various skin diseases have also been

associated with eosinophilia, including atopic dermatitis, eczema, pemphigus, urticaria, and toxic epidermal necrolysis.

Infectious Diseases.

Eosinophilia is often associated with infection with multicellular helminthic parasites. The level of eosinophilia tends to parallel the magnitude and extent of tissue invasion, especially by larvae. Eosinophilia often does not occur in established parasitic infections that are well contained within tissues or are solely intraluminal in the gastrointestinal tract, such as *Giardia lamblia* and *Enterobius vermicularis.*

In evaluating patients with unexplained eosinophilia, the dietary history and geographic or travel history may indicate potential exposures to helminthic parasites. It is frequently necessary to examine the stool for ova and larvae at least three times. Additionally, the diagnostic parasite stages of many of the helminthic parasites that cause eosinophilia never appear in feces. Thus, normal results of stool examinations do not absolutely preclude a helminthic cause of eosinophilia, and diagnostic blood tests or tissue biopsy may be needed.

Two fungal diseases may be associated with eosinophilia: aspergillosis in the form of allergic bronchopulmonary aspergillosis (Chapter 218.1) and coccidioidomycosis (Chapter 221) following primary infection, especially in conjunction with erythema nodosum.

Hypereosinophilic Syndrome.

The idiopathic hypereosinophilic syndrome is a leukoproliferative disease characterized by sustained overproduction of eosinophils. The three diagnostic criteria for this disorder are (1) eosinophilia of greater than 1,500 cells/µL persisting for longer than 6 mo, (2) lack of another diagnosis to explain the eosinophilia, and (3) signs and symptoms of organ involvement. The clinical signs and symptoms of hypereosinophilic syndrome can be heterogeneous because of the diversity of potential organ involvement. Eosinophilic leukemia may be distinguished from idiopathic hypereosinophilic syndrome by demonstrating probable clonality of X-linked polymorphisms in female patients by using purified populations of eosinophils. One of the most serious and life-threatening complications is cardiac disease due to endomyocardial thrombosis and fibrosis. Other organ systems that can be involved can include the skin, liver, spleen, gastrointestinal tract, brain, and lungs. Therapy is aimed at suppressing eosinophilia and is initiated with corticosteroids. Hydroxyurea or a-interferon may be beneficial in patients unresponsive to corticosteroids. The underlying causes of hypereosinophilic syndrome remain unknown. For patients with prominent organ involvement and those who fail to respond to therapy, the mortality is approximately 75% after 3 years.

Miscellaneous Diseases.

Eosinophilia is observed in many patients with primary immunodeficiency syndromes, especially hyper IgE syndrome (Chapter 116) and Wiskott-Aldrich syndrome. Eosinophilia is also frequently present in syndromes of thrombocytopenia with absent radii and in familial reticuloendotheliosis with eosinophilia. Mild eosinophilia is found in 20% of patients with Hodgkin's disease and in gastrointestinal disorders including ulcerative colitis, Crohn's disease during symptomatic phases, gastroenteritis that is associated with milk precipitins, and chronic hepatitis.

Chapter 120 - Disorders of Phagocyte Function

Laurence A. Boxer

Neutrophils are particularly important in protecting the skin, mucous membranes, and lining of the respiratory and gastrointestinal tracts as part of the first line of defense against microbial invasion. During the critical 2–4-hr period after microbial tissue invasion, phagocytic cells must arrive at the site of inflammation if the infection is to be contained. If not, the resulting infection extends to a larger local lesion and potentially disseminates hematogenously.

Immunologic evaluation of patients with suspected immunodeficiency is formidable (Chapter 112), especially those presenting with recurrent or unusual bacterial infections suggesting disorders of phagocyte function (Table 120–1). The differential diagnosis of diseases can be complicated by similar presentations of neutrophil defects or antibody or complement deficiency. Disorders of phagocyte function should be considered if results of initial screening tests are normal and the patient has had recurrent or unusual bacterial infections (Fig. 120–1). Despite the rarity of the inherited phagocyte disorders, the understanding gleaned from evaluating the molecular mechanisms underlying the inherited disorders has contributed immensely to our knowledge of normal neutrophil function.

Chemotaxis, the direct migration of cells into sites of infection, involves a complex series of events (Chapter 117). Studies of defective in vitro chemotaxis of neutrophils obtained from children having various clinical conditions have not established whether the increased number of infections arises from a chemotactic abnormality or secondary to medical complications of the underlying disorder. The hyper IgE syndrome is characterized by reduced neutrophil motility accompanied by markedly elevated levels of IgE leading to chronic dermatitis and recurrent sinopulmonary infections and is associated with coarse facial features, retention of primary teeth, and a propensity for recurrent bone fractures (Chapter 116).

LEUKOCYTE ADHESION DEFICIENCY

Leukocyte adhesion deficiency–1 (LAD-1) and -2 (LAD-2) are rare autosomal recessive disorders of leukocyte function. LAD-1 affects about 1 per 10 million individuals and is characterized by recurrent bacterial and fungal infections and depressed inflammatory responses despite striking blood neutrophilia.

Genetics and Pathogenesis.

LAD-1 results from mutations of the gene on chromosome 21q22.3 encoding CD18, the 95-kD $ß_2$ leukocyte integrin subunit. Normal neutrophils express three heterodimeric adhesion molecules known as LFA-1 (CD11a/CD18), Mac-1 (CD11b/CD18, also known as CR3 or iC3b receptor), and p150, 95 (CD11c/CD18). These three transmembrane adhesion molecules are composed of unique a_1 subunits of 185, 190, and 150?kD, respectively, encoded on chromosome 16 and sharing a common $ß_2$ subunit. This group of leukocyte integrins is responsible for the tight adhesion of neutrophils to the endothelial cell surface, egress from the circulation, and adhesion to iC3b-coated microorganisms, which promotes phagocytosis and particulate activation of the nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase.

Mutations in the CD18 gene either impair or prevent mRNA production or affect the structure of the synthesized CD18 peptide, leading to abnormal post-translational processing and loss of the abnormal CD11/CD18. The $CD11a_1$ subunits are not stable as polymers, resulting in deficiency of LAD-1 neutrophils in the three $CD11a_1$ subunits. Some mutations of CD11/CD18

TABLE 120-1 -- Disorders of Phagocyte Function

Disorder	Etiology	Impaired Function	Clinical Consequence
Degranulation Abnormalities			
Chédiak-Higashi syndrome	Autosomal recessive; disordered coalescence of lysosomal granules. Responsible gene found at 1q42–45. The encoded protein has structural features homologous to a vacuolar sorting protein.	Decreased neutrophil chemotaxis, degranulation and bactericidal activity; platelet storage pool defect; impaired NK function, failure to disperse melanosomes.	Neutropenia; recurrent pyogenic nfections, propensity to develop marked hepatosplenomegaly in the accelerated phase; pigment dilution in the skin and fundus.

Specific granule deficiency	Autosomal recessive; abnormal regulation of various myeloid granule genes by a transacting factor.	Impaired chemotaxis and bactericidal activity; bilobed nuclei in neutrophils; reduced content of neutrophil defensins, gelatinase, collagenase, vitamin B_{12} -binding protein, lactoferrin.	Recurrent deep-seated abscesses.
Adhesion Abnormalities			
Leukocyte adhesion deficiency 1	Autosomal recessive; absence of CD11/CD18 surface adhesive glycoprotein (β_2 integrins) on leukocyte membranes most commonly arising from failure to express CD18 mRNA.	Decreased binding of C3bi to neutrophils and impaired adhesion to ICAM1 and ICAM2.	Neutrophilia; recurrent bacterial infection without pus formation.
Leukocyte adhesion deficiency 2	Autosomal recessive; absence of neutrophil sialyl-Lewis X.	Decreased adhesion to activated endothelium expressing ELAM.	Neutrophilia; recurrent bacterial infection without pus formation.
Neutrophil actin dysfunction	Altered polymerization of neutrophil cytoplasmic actin; perhaps arising from the presence of an inhibitor to F-actin formation.	Impaired neutrophil adhesion, chemotaxis, and bacterial killing.	Neutrophilia; recurrent bacterial infections without pus formation.
Disorders of Cell Motility			
Enhanced motile responses: Familial Mediterranean Fever (FMF)	Autosomal recessive gene responsible for FMF on chromosome 16, which encodes for a protein called pyrin that may modify neutrophil activation.	Excessive accumulation of neutrophils at inflamed sites.	Recurrent fever, peritonitis, pleuritis, arthritis, and amyloidosis.
Depressed Motile Responses			
Defects in the generation of chemotactic signals	IgG deficiencies; C3 and properdin deficiency can arise from genetic or acquired abnormalities; mannose binding protein deficiency predominantly in neonates.	Deficiency of serum chemotaxis and opsonic activities.	Recurrent pyogenic infections.
Intrinsic defects of the neutrophil, e.g., leukocyte adhesion deficiency, Chédiak-Higashi syndrome, specific granule deficiency, neutrophil actin dysfunction, neonatal neutrophils	In the neonatal neutrophil there is diminished ability to express (β_2 -integrins and there is a qualitative impairment in (β_2 -integrin function.	Diminished chemotaxis.	Propensity to develop pyogenic infections.
Direct inhibition of neutrophil mobility, e.g., drugs	Ethanol, glucocorticoids, cyclic AMP.	Impaired locomotion and ingestion. Impaired adherence.	Possible cause for frequent infections; neutrophilia seen with epinephrine is the result of cyclic AMP release from endothelium.
Immune complexes	Bind to Fc receptors on neutrophils in patients with rheumatoid arthritis, systemic lupus erythematosus, other inflammatory states.	Impaired chemotaxis.	Recurrent pyogenic infections.
Hyperimmunoglobulin E syndrome	Autosomal dominant; variable expression of a soluble inhibitor from mononuclear cells affecting neutrophil chemotaxis; high levels of antistaphylococcal IgE.	Impaired chemotaxis at times; impaired IgG opsonization of *Staphylococcal aureus*.	Recurrent skin and senopulmonary infections.
Defects of Microbicidal Activity			

Chronic granulomatous disease	X-linked and autosomal recessive; failure to express functional gp91^{phox} in the phagocyte membrane in p22^{phox} (autosomal recessive). Other autosomal recessive forms of CGD arise from failure to express protein p47^{phox} or p67^{phox} .	Failure to activate neutrophil respiratory burst leading to failure to kill catalase-positive microbes.	Recurrent pyogenic infections with catalase-positive microorganisms.
G-6-PD deficiency	Less than 5% of normal activity of G-6-PD.	Failure to activate NADPH-dependent oxidase.	Infections with catalase positive microorganisms.
Myeloperoxidase deficiency	Autosomal recessive; failure to process modified precursor protein arising from missense mutation.	H_2O_2 -dependent antimicrobial activity not potentiated by myeloperoxidase.	None.
Rac-2 deficiency	Autosomal recessive; dominant negative inhibitor by mutant protein of *Rac-2* mediated functions.	Absent receptor mediated O_2 -generation and chemotaxis. Impaired neutrophil rolling on endothelium.	Neutrophilia; recurrent bacterial infections
Deficiencies of glutathione reductase and glutathione synthetase	Failure to detoxify H_2O_2 .	Excessive formation of H_2O_2 .	Minimal problems with recurrent pyogenic infections.
Impaired Macrophage Function			
Defects in the interferon ?–interleukin-12 axis	Interferon ?-receptor ligand- binding chain, interferon ?-receptor signalling chain, interleukin-12-receptor ß1 chain, interleukin-12p40 deficiency. The interferon ?-receptor abnormalities may be inherited in an autosomal dominant or recessive fashion. The interleukin ?-12 receptor as well as interleukin-12 are inherited in an autosomal recessive fashion.	Impaired killing of microorganisms. Fatal BCG infection secondary to inability to either produce interleukin-12 by dendritic cells and macrophages which is necessary to induce secretion of interferon ? by T cells and natural killer cells or secondary to depressed bactercidal activity of macrophages lacking normal function of interferon-? receptor.	Infection with atypical mycobacteria, *Salmonella*, and *Listeria*.
Impaired Spleen Function			
Splenic absence or splenic dysfunction	Congenital absence of spleen, removal of spleen, vascular occlusion of spleen.	Removal or impaired function of splenic macrophages.	Propensity to infection with encapsulated bacteria.

X = X-linked; AR = autosomal recessive; G-6-PD = glucose-6-phosphate dehydrogenase; CGD = chronic granulomatous disease; ICAM = intracellular adhesion molecule; NK = natural killer; C = complement; m = messenger; H_2O_2 = hydrogen peroxide; NADPH = nicotinamide-adenine dinucleotide phosphate; AMP = adenosine phosphate; BCG = bacille Calmette-Guérin, phox = phagocyte oxidase.

Modified from Boxer LA: Quantitative abnormalities of granulocytes. In Beutler E, Lichtman MA, Coller BS, et al (editors): Williams Hematology, 6th ed. New York, McGraw-Hill, 2001, p 836.

Figure 120-1 Algorithm for the evaluation of the patient with recurrent infections suggesting disorders of phagocyte function. CBC = complete blood count; Ig = immunoglobulin; G-6-PD = glucose-6-phosphate dehydrogenase; LAD = leukocyte adhesion deficiency. New York, McGraw-Hill, 1985, p 144.)

allow a low level of assembly and functional active integrin molecules. These children retain some neutrophil integrin adhesion function and have a moderate phenotype. In contrast, failure of neutrophils to bear the β_2 integrins leads to inability to migrate to sites of inflammation outside of the lung because of their inability to adhere firmly to surfaces and undergo transendothelial migration. Failure of the CD11/CD18–deficient neutrophils to undergo transendothelial migration occurs because the β_2 integrins bind to intercellular adhesion molecules–1 and –2 (ICAM-1 and ICAM-2) expressed on inflamed endothelial cells. The neutrophils that do arrive at inflammatory sites in the lungs by CD11/CD18-independent processes fail to recognize microorganisms coated with the opsonin complement fragment iC3b, which is an important stable opsonin formed by the cleavage of C3b by C3b inactivator. Other neutrophil functions such as degranulation and oxidative metabolism normally triggered by iC3b binding are also diminished and markedly compromised in neutrophils from patients with LAD-1 deficiency. Impairment in neutrophil function underlies the propensity for serious and recurrent bacterial infections that is the clinical expression of this disease.

Monocyte function is also impaired, with poor fibrinogen-binding function, an activity promoted by the CD11/CD18 complex; consequently, such cells are unable to participate effectively in wound healing.

Children with LAD-2 share the clinical features of LAD-1 but have normal CD11/CD18 integrins. Features unique to LAD-2 are neurologic defects, cranial facial dysmorphism, and Bombay erythrocyte phenotype. The primary deficiency in LAD-2 is a defect in a specific GDP-L-fucose transporter of the Golgi apparatus. This abnormality prevents the incorporation of fucose into various glycoproteins, which are expressed on cell surface membranes. This provides a biochemical basis both for the abnormalities of erythrocyte carbohydrate blood group markers and the defects in neutrophil adhesion. The neutrophils from patients with LAD-2 are deficient in the carbohydrate structure sialyl-Lewis X, which renders the cells unable to adhere to activated endothelial cells. Thus, the neutrophils from these patients are unable to tether to inflamed venules for subsequent activation and spreading on the endothelium.

Clinical Manifestations.

Patients with the severe clinical form of LAD-1 express less than 0.3% of the normal amount of the β_2 integrin molecules, whereas patients with the moderate phenotype may express 2–7%. Children with severe disease present in infancy with recurrent, indolent bacterial infections of the skin, mouth, respiratory tract, lower intestinal tract, and genital mucosa. They may have a history of delayed separation of the umbilical cord, usually with associated infection of the cord stump. Skin infection may progress to large chronic ulcers with polymicrobial infection, including anaerobic organisms. The ulcers heal slowly, require months of antibiotic treatment, and often require plastic surgical grafting. Severe gingivitis similar to what occurs in patients with profound neutropenia is common, with early loss of primary and then secondary teeth.

The pathogens infecting patients with LAD-1 are similar to those affecting patients with severe neutropenia (Chapter 121) and include *Staphylococcus aureus* and enteric gram-negative organisms such as *Escherichia coli*. These patients are also susceptible to fungal infections such as *Candida* and *Aspergillus*. As in profound neutropenia, the typical signs of inflammation, swelling, erythema, and warmth, may be absent. Pus does not form, and few neutrophils may be identified microscopically in biopsy specimens of infected tissues. Despite the paucity of neutrophils within the affected tissue, the circulating neutrophil count during infection may typically exceed 30,000/µL and can surpass 100,000/µL. During intervals between infection, the peripheral blood neutrophil count may chronically exceed 12,000/µL. LAD-1 genotypes, producing small amounts of functional integrins at the surface of the neutrophil, significantly reduce the severity and frequency of infections compared to children with the severe form.

Laboratory Findings.

The diagnosis of LAD-1 is established most readily by flow cytometric measurements of surface CD11b in stimulated and unstimulated neutrophils using monoclonal antibodies directed against CD11b. Assessment of neutrophil and monocyte adherence, aggregation, chemotaxis, and iC3b-mediated phagocytosis generally demonstrates striking abnormalities that directly correspond to the molecular deficiency. Delayed-type hypersensitivity reactions are normal, and most individuals have normal specific antibody synthesis. Some patients, however, have impaired T lymphocyte–dependent antibody responses that can be demonstrated by suboptimal responses to repeat vaccination with tetanus toxoid, diphtheria toxoid, and poliovirus. The diagnosis of LAD-2 is established by demonstrating the lack of sialyl-Lewis X on the neutrophil.

Treatment.

Treatment of LAD-1 depends on the phenotype as determined by the level of expression of functional CD11/CD18 integrins. Early allogeneic bone marrow transplantation is the treatment of choice for severe LAD-1 associated with complete absence of the CD11/CD18 integrins. Other treatment is largely supportive. Patients can be maintained on prophylactic trimethoprim-sulfamethoxazole and should have close surveillance to identify infections early. Broad-spectrum antibiotics are indicated for empirical therapy when infection occurs. Determination of the etiologic agent by culture and biopsy is important because of the prolonged antibiotic treatment required for indolent infections.

Although gene replacement therapy is not yet available, LAD-1 is an ideal candidate for this approach because the clinical history and mild forms of LAD-1 support the notion that even a low-level correction of neutrophil function attenuates the severity of the disease. One patient but not others responded to fucose supplementation, which induced a rapid reduction in the circulating leukocyte count and appearance of the sialyl-Lewis X molecules accompanied with marked improvement in leukocyte adhesion.

Prognosis.

The severity of infectious complication correlates with the degree of β_2 integrin deficiency. Patients with severe deficiency may die in infancy, and those surviving infancy have a susceptibility to severe life-threatening systemic infections. Patients with moderate deficiency have infrequent life-threatening infections and relatively

long survival.

CHÉDIAK-HIGASHI SYNDROME

Chédiak-Higashi syndrome (CHS) is a rare autosomal recessive disorder characterized by increased susceptibility to infection owing to defective degranulation of neutrophils, a mild bleeding diathesis, partial oculocutaneous albinism, progressive peripheral neuropathy, and a tendency to develop a life-threatening lymphoma-like syndrome. CHS was initially recognized by giant cytoplasmic granules in neutrophils, monocytes, and lymphocytes but is now recognized as a disorder of generalized cellular dysfunction characterized by increased fusion of cytoplasmic granules. Pigmentary dilution involving the hair, skin, and ocular fundi results from pathologic aggregation of melanosomes and is associated with a failure of decussation of the optic and auditory nerves. Patients exhibit an increased susceptibility to infection that can be explained in part by defects in neutrophil chemotaxis, degranulation, and bactericidal activity. The presence of giant granules in the neutrophils interferes with the cell's ability to traverse the narrow passages between endothelial cells into tissue.

Genetics and Pathogenesis.

The mutated gene for CHS, located at chromosome 1q2–q44, has been cloned on the basis of its homology

to the murine gene responsible for mouse CHS (beige phenotype). It has structural features homologous to a vacuolar sorting protein termed VPS15 in yeast. The CHS protein is thought to be associated with vesicle transport and to mediate protein-protein interaction and protein-membrane associations.

Almost all cells of patients with CHS show some aspect of the oversized and dysmorphic lysosomes, storage granules, or related vesicular structures. Melanosomes or melanocytes are oversized, and delivery to the keratinocytes and hair follicles is compromised because of the failure to properly disperse the giant melanosomes, resulting in hair shafts devoid of pigment granules. This leads to the macroscopic impression of hair and skin that is lighter than expected from parental coloration. The same abnormality in melanocytes leads to the partial ocular albinism associated with light sensitivity.

Beginning early in neutrophil development there is spontaneous fusion of giant primary granules with each other or with cytoplasmic membrane components, resulting in huge secondary lysosomes that contain reduced content of hydrolytic enzymes including proteinases, elastase, and cathepsin G. In turn, the deficiency of proteolytic enzymes may be responsible for the impaired killing of microorganisms by CHS neutrophils. Because the CHS blood cell membranes are more fluid than cells of normal individuals, it is possible that the altered membrane structure could lead to defective regulation of membrane activation. Changes in membrane fluidity may conceivably affect cell function by altering expression of membrane receptors. This could result in the elevated levels of intracellular cyclic adenosine monophosphate, disordered assembly of microtubules, and defective interaction of microtubules with lysosome membranes, which has been reported.

Clinical Manifestations.

Patients with CHS have light skin and silvery hair, and frequently complain of solar sensitivity and photophobia. Other signs and symptoms vary considerably, but frequent infections and neuropathy are common. The infections involve mucous membranes, skin, and respiratory tract. Affected children are susceptible to gram-positive and gram-negative bacteria and fungi, with *S. aureus* being the most common offending organism. The neuropathy may be sensory or motor in type, and ataxia may be a prominent feature. Neuropathy often begins in the teenage years and becomes the most prominent problem.

Patients with CHS have prolonged bleeding times with normal platelet counts, resulting in impaired platelet aggregation associated with a deficiency of the dense granules containing adenosine diphosphate and serotonin. Natural killer cell function is also impaired.

The most life-threatening complication of CHS is the development of an accelerated phase of a lymphoma-like syndrome characterized by pancytopenia, high fever, and lymphohistiocytic infiltration of liver, spleen, and lymph nodes. The accelerated phase may occur at any age. The onset of this accelerated phase may be related to the inability of these patients to contain and control Epstein-Barr virus infection, which leads to features simulating virus-associated hemophagocytic syndrome. The lymphocytic proliferation is associated with recurrent bacterial and viral infections and usually results in death. At autopsy, the lymphohistiocytic infiltrates in the liver, spleen, and lymph nodes are extensive but are not neoplastic by histopathologic criteria.

Laboratory Findings.

The diagnosis of CHS is established by finding large inclusions in all nucleated blood cells. These can be seen on Wright-stained blood films but are accentuated by a peroxidase stain.

Treatment.

High-dose ascorbic acid (200?mg/24?hr for infants, 2,000?mg/24?hr for adults) improves the clinical status of some children in the stable phase. Although controversy surrounds the efficacy of ascorbic acid, given the safety of the vitamin, it is reasonable to administer ascorbic acid to all patients.

The only curative therapy for the accelerated phase is bone marrow transplantation from an HLA-compatible donor or an unrelated donor compatible at the D locus. Marrow transplantation reconstitutes normal hematopoietic and immunologic function and corrects the natural killer cell deficiency in patients entering the accelerated phase. However, bone marrow transplantation does not correct or prevent the peripheral neuropathy.

MYELOPEROXIDASE DEFICIENCY

Myeloperoxidase (MPO) deficiency is a disorder of oxidative metabolism and is one of the most common inherited disorders of phagocytes, occurring at a frequency approaching 1 per 4,000 individuals. MPO is a green heme protein located in the azurophilic lysosomes of neutrophils and monocytes and is the basis for the greenish tinge to pus accumulated at a site of infection. Most individuals with the trait do not have an increased rate of infection or other clinical manifestations of disease.

Genetics and Pathogenesis.

Mutations in the MPO gene causing this defect have been defined and provide insight into the post-translational processing of this granule protein. MPO mRNA is transcribed exclusively during the promyelocytic stage of granulopoiesis. The primary translation product of the MPO gene is a single-chain peptide of 80?kD that undergoes co-translational glycosylation followed by a series of modifications of the oligosaccharides. MPO deficiency is caused by a missense mutation in the MPO gene that replaces an arginine with tryptophan and results in an MPO precursor that does not incorporate heme. Although this mutation is the most common cause of MPO deficiency, many patients are compound heterozygotes with one allele bearing the common mutation and the other being normal or possessing a mutation not yet identified. A partial deficiency results if only one allele is normal.

Partial or complete MPO deficiency leads to diminished production of hypochlorous acid (HOCl) and HOCl-derived chloramines. The deficiency in HOCl leads to early depression of gram-positive and gram-negative bacterial rates of killing in vitro that normalizes after 1?hr incubation. These data indicate that deficient cells use an MPO-independent microbicidal system that is slower to kill pathogens than the MPO-H_2O_2 -halide system used by normal neutrophils.

Clinical Manifestations.

MPO deficiency usually is clinically silent. Rarely, patients may have disseminated candidiasis, usually in conjunction with diabetes mellitus. Acquired partial MPO deficiency can develop in acute myelogenous leukemia and in myelodysplastic syndromes.

Laboratory Findings.

Deficiency of neutrophil and monocyte MPO can be identified by histochemical analysis.

Treatment.

There is no specific therapy. Aggressive treatment with antifungal agents should be used in patients with candidal infections. The prognosis is usually excellent.

CHRONIC GRANULOMATOUS DISEASE

Chronic granulomatous disease (CGD) is characterized by the ability of neutrophils and monocytes to ingest but their inability to kill **catalase-positive microorganisms** because of a defect in the generation of microbial oxygen metabolites. CGD is a rare disease with an incidence of 4–5 per million individuals, caused by genes affecting one X-linked and three autosomal recessive chromosomes.

Genetics and Pathogenesis.

Activation of NADPH oxidase requires stimulation of the neutrophils and involves assembly from cytoplasmic and integral membrane subunits. Oxidase activation initially arises from phosphorylation of a cationic cytoplasmic

---

716

protein, $p47^{phox}$ (47kd "phagocyte oxidase" protein). Phosphorylated $p47^{phox}$ together with two other cytoplasmic components of the oxidase, $p67^{phox}$ and a low molecular weight guanine triphosphatase (Rac-2), translocates to the membrane where they interact with the cytoplasmic domains of the transmembrane flavocytochrome b_{558} to form the active oxidase (see Fig. 117–5). The flavocytochrome is a heterodimer of two peptides, $p22^{phox}$ and highly glycosylated $gp91^{phox}$. Current models are consistent with three transmembrane domains within the N-terminus of the flavocytochrome that contain the histidines that coordinate heme binding. The role of $p22^{phox}$ peptide is required for stability of $gp91^{phox}$ and for oxidase activity. The role of $p40^{phox}$ in oxidase activation remains unclear. The $gp91^{phox}$ peptide is required for electron transport through use of an NADPH-binding domain, a flavin-binding domain, and a heme-binding domain. In turn, the $gp91^{phox}$ is stabilized by $p22^{phox}$. Furthermore, $p22^{phox}$ provides a docking site for the cytoplasmic subunits. The cytoplasmic $p47^{phox}$, $p67^{phox}$, and Rac-2 appear to serve as regulatory elements for activation of cytochrome b_{558} .

Approximately two thirds of patients with CGD are males who inherit their disorder as a result of mutations in the X-chromosome gene encoding $gp91^{phox}$. About one third of patients inherit CGD in an autosomal recessive fashion resulting from mutations in the gene encoding $p47^{phox}$ on chromosome 7. Defects in the genes encoding $p67^{phox}$ (chromosome 1) or $p22^{phox}$ (chromosome 16) also occur; these are inherited in an autosomal recessive manner and account for about 5% of cases of CGD.

Effective neutrophil phagocytosis requires activation of NADPH-dependent oxidase (Chapter 117). After activation of neutrophils, electrons are passed from NADPH to flavin and then to the heme prosthetic group on cytochrome b_{558} and finally to molecular oxygen to form O_2^- mutations in the gene for cytochrome b_{558} . Alternatively, the cytosolic factor renders the electron transport system ineffective in generating O_2^- .

The metabolic deficiency of the CGD neutrophil predisposes the host to infection; the CGD phagocytic vacuoles remain acidic, and the bacteria are not digested properly (Fig. 120–2). Hematoxylin-eosin–stained sections from patients' macrophages may contain a golden pigment that reflects this abnormal accumulation of ingested material and contributes to the diffuse granulomas that give CGD its descriptive name.

Clinical Manifestations.

Although the clinical presentation is variable, several features suggest the diagnosis of CGD. Any patient with recurrent or unusual lymphadenitis, hepatic abscesses, osteomyelitis at multiple sites, a family history of recurrent infections, or unusual infections with catalase-positive organisms (e.g., *S. aureus*) require evaluation for this disorder.

The onset of clinical signs and symptoms may occur from early infancy to young adulthood. The attack rate and severity of infections are exceedingly variable. The most common pathogen is *S. aureus,* although any catalase-positive microorganism may be involved. Other organisms frequently causing infections include *Serratia marcescens, Burkholderia cepacia, Aspergillus*, *Candida albicans,* and *Salmonella*. Pneumonias, lymphadenitis, and skin infections are the most common illnesses encountered. Patients may suffer from the sequelae of chronic infection, including anemia of chronic disease, lymphadenopathy, hepatosplenomegaly, chronic purulent dermatitis, restrictive lung disease, gingivitis, hydronephrosis, and pyloric outlet narrowing. Perirectal abscesses and recurrent skin infections, including folliculitis, cutaneous granulomas, and discoid lupus erythematosus also suggest the possibility of CGD. Granuloma formation and inflammatory processes are a hallmark of CGD and may be the presenting symptoms that prompt testing for CGD if they cause pyloric outlet obstruction, bladder outlet obstruction, or rectal fistulae simulating Crohn disease.

Figure 120-2 The pathogenesis of chronic granulomatous disease (CGD). The manner in which the metabolic deficiency of the CGD neutrophil predisposes the host to infection is shown schematically. Normal neutrophils stimulate hydrogen peroxide in the phagosome containing ingested *Escherichia coli*. Myeloperoxidase is delivered to the phagosome by degranulation, as indicated by the closed circles. In this setting, hydrogen peroxide acts as a substrate for myeloperoxidase to oxidize halide to hypochlorous acid and chloramines that kill the microbes. The quantity of hydrogen peroxide produced by the normal neutrophil is sufficient to exceed the capacity of catalase, a hydrogen peroxide–catabolizing enzyme of many aerobic microorganisms, including most gram-negative enteric bacteria, *Staphylococcus aureus, Candida albicans*, and *Aspergillus*. When organisms such as *E. coli* gain entry into CGD neutrophils, they are not exposed to hydrogen peroxide because the neutrophils do not produce it, and the hydrogen peroxide generated by microorganisms themselves is destroyed by their own catalase. When CGD neutrophils ingest streptococci, these organisms, which lack catalase, generate enough hydrogen peroxide to result in a microbicidal effect. As indicated (*middle*), catalase-positive microbes such as E. coli can survive within the phagosome of the CGD neutrophil. Modified from Boxer LA: Quantitative abnormalities of granulocytes. In Beutler E, Lichtman MA, Coller BS, Kipps TJ, Seligsohn V [editors]: *Williams Hematology,* 6th ed. New York, McGraw-Hill, 2001, p 845.)

Laboratory Findings.

For screening of CGD, the **nitroblue tetrazolium (NBT) dye test** is still widely used, but it is rapidly being replaced by the more accurate flow cytometry test using **dihydrorhodamine 123 fluorescence (DHR test).** DHR detects oxidant production because it increases fluorescence when oxidized by H_2O_2 .

Neutrophils from patients with CGD have normal glucose-6-phosphate dehydrogenase (G6PD) activity. However, a few individuals with apparent CGD have been described as having neutrophils deficient in G6PD activity. The erythrocytes of these patients also lack the enzyme, and the patients have chronic hemolysis. CGD and G6PD deficiency can be distinguished by the hemolytic anemia associated with G6PD deficiency and by the normal erythrocyte G6PD activity in CGD compared with the markedly reduced activity in G6PD deficiency.

Treatment.

Bone marrow transplantation is the only known cure for CGD. Vigorous supportive care along with recombinant interferon-? is used before transplantation. As part of supportive care, patients with CGD should be given daily oral trimethoprim-sulfamethoxazole for prophylaxis of infections. Cultures must be obtained as soon as infection is suspected. Most abscesses require surgical drainage for therapeutic and diagnostic purposes. Prolonged use of antibiotics is often required. If fever occurs without an obvious focus, it is advisable to consider the use of radiographs of the chest and skeleton as well as CT

scans of the liver to determine if pneumonia, osteomyelitis, or liver abscesses are present. The cause of fever cannot always be established, and empirical treatment with broad-spectrum parental antibiotics is often required. The erythrocyte sedimentation rate (ESR) may be used to help determine the duration of antibiotic treatment.

Aspergillus infection requires treatment with amphotericin B. Corticosteroids may also be useful for the treatment of children with antral and urethral obstruction. Granulomas may be sensitive to low doses of prednisone (0.5?mg/kg/24?hr); treatment should be tapered over several weeks.

Interferon-? (50?µg/m^2 , 3 times/wk) can reduce the number of serious infections. The mechanism of action of interferon-? therapy in CGD is unknown. In the future, somatic gene therapy may be used to correct defective phagocyte oxidase function in selected patients with CGD.

GENETIC COUNSELING.

Identifying a patient's specific genetic subgroup is useful primarily for genetic counseling and prenatal diagnosis. In cases of suspected X-linked CGD, further analysis is not necessary if the fetus is initially demonstrated to be a 46,XX female. Fetal blood sampling and NBT slide test analysis of fetal neutrophils can be used for prenatal diagnosis of CGD. DNA analysis of amniotic fluid cells or chorionic villus biopsy is an option for early prenatal diagnosis. Restriction fragment polymorphisms

have been identified for gp91phox and p67phox and have proved useful for diagnosis. In families in which the specific mutation is known, prenatal diagnosis is established by analysis of fetal DNA for the presence of mutant alleles using the polymerase chain reaction.

Prognosis.

The overall mortality rate for CGD is about 2 patient deaths/year/100 cases, with the highest mortality among young children. The long-term prognosis for patients with CGD has greatly improved during the past 20 yr. This can be attributed to an increased understanding of the biology of CGD, the development of effective infection prophylactic regimens, close surveillance for signs of infections, and aggressive surgical and medical interventions.

Chapter 121 - Leukopenia

Laurence A. Boxer

Marked developmental changes in normal values for the total white blood cell (WBC) count occur during childhood (Chapter 710). The mean WBC count at birth is high, followed by a rapid fall beginning at 12?hr until the end of the first week. Thereafter, values are stable until 1 yr of age. A slow, steady decline in the WBC count continues throughout childhood until the adult value is reached in adolescence. Leukopenia in adults is defined as a total WBC count less than 4,000/µL. Evaluation of patients with leukopenia, neutropenia, or lymphopenia begins with a through history, physical examination, family history, and screening laboratory tests (Fig. 121–1).

NEUTROPENIA

Neutropenia is an **absolute neutrophil count (ANC)**, calculated as the WBC count/µL × per cent of neutrophils and bands, more than two standard deviations below the normal mean. Normal neutrophil counts must be stratified for age and race. For whites, the lower limit of normal for the neutrophil count is 1,500/µL; for blacks, the lower limit of normal is 1,200/µL. The relatively low counts in blacks probably reflect a relative decrease in neutrophils in the storage compartment of the bone marrow.

Etiology.

Acute neutropenia evolving over a few days often occurs when neutrophil use is rapid and production is compromised. **Chronic neutropenia** lasting months or years usually arises from reduced production or excessive splenic sequestration of neutrophils. Neutropenia may be classified by whether it arises secondary to factors extrinsic to marrow myeloid cells (Table 121–1), which is common; as an acquired disorder of myeloid and stem cells (Table 121–2), which is less common; or more rarely an intrinsic defect affecting proliferation and maturation of myeloid and stem cells (Table 121–3).

Neutropenia may be characterized as mild, with an ANC of 1,000–1,500/µL; moderate, with an ANC of 500–1,000/µL; or severe, with an ANC <500/µL. This stratification aids in predicting the risk of pyogenic infection because only patients

with severe neutropenia have significantly increased susceptibility to life-threatening infections.

INFECTIOUS CAUSES.

Transient neutropenia often accompanies viral infections. Neutropenia associated with common childhood viral disease occurs during the first 1–2 days of illness and may persist for 3–8 days. It usually corresponds to a period of acute viremia and is related to virus-induced redistribution of neutrophils from the circulating to the marginating pool. Neutrophil sequestration possibly occurs after virus-induced tissue damage. Moderate to severe neutropenia may also be associated with a wide variety of other infectious causes (Table 121–4). Bacterial sepsis is a particularly serious cause of neutropenia.

Chronic neutropenia often accompanies infection with human immunodeficiency virus (HIV)–1 as a finding associated with AIDS. The neutropenia associated with AIDS probably arises from a combination of impaired neutrophil production and the accelerated destruction of neutrophils mediated by antineutrophil antibodies.

DRUG-INDUCED NEUTROPENIA.

Drug use remains one of the most common causes of neutropenia (Table 121–5). The incidence of drug-induced neutropenia increases precipitously with age; only 10% of cases occur among children and young adults, with the majority of cases among adults. Drug-induced neutropenia has several underlying mechanisms (i.e., immune-mediated, toxic, idiosyncratic, and hypersensitivity reactions) and should be differentiated from the severe neutropenia that predictably occurs after large doses of cytoreductive cancer drugs or radiotherapy. Cytotoxic chemotherapy preferentially affects myeloid cells and induces neutropenia because of the high proliferative rate of neutrophil precursors and the rapid turnover of blood neutrophils.

Immune-mediated neutropenia usually lasts for about 1 wk and is thought to arise from effects of drugs, such as propylthiouracil or penicillin, that act as haptens to stimulate antibody formation. Other drugs, including the antipsychotic drugs such as the phenothiazines, can cause neutropenia when given in toxic amounts. In contrast, idiosyncratic reactions, such as to chloramphenicol, are unpredictable with regard to dose or duration of use. Hypersensitivity reactions are rare and occasionally may involve arene oxide metabolites of aromatic anticonvulsants.

Figure 121-1 Algorithm for the evaluation of a patient with leukopenia. ANC = absolute neutrophil count; NK = natural killer; WBC = white blood cell count. TABLE 121-1 -- Causes of Neutropenia Extrinsic to Bone Marrow Myeloid Cells

Cause	Etiologic Factors/Agents	Associated Findings
Infection	Viral, bacterial, protozoal, rickettsial, fungal	Redistribution from circulating to marginating pools, impaired production, accelerated destruction
Drug induced	Phenothiazines, sulfonamides, anticonvulsants, penicillins, aminopyrines	Hypersensitivity reaction (fever, lymphadenopathy, rash, hepatitis, nephritis, pneumonitis, aplastic anemia), antineutrophil antibodies
Immune neutropenia	Isoimmune; autoimmune	Variable arrest from metamyelocyte to segmented neutrophils in bone marrow
Reticuloendothelial sequestration	Hypersplenism	Anemia, thrombocytopenia
Bone marrow replacement	Malignancy (leukemia, lymphoma, metastatic solid tumors), Gaucher disease, granuloma, fibrosis	Anemia, thrombocytopenia, presence of immature myeloid and erythroid precursor in peripheral blood
Cancer chemotherapy or radiation therapy to bone marrow	Suppression of myeloid cell production	Bone marrow hypoplasia, anemia, thrombocytopenia
Ineffective myelopoiesis	Malnutrition (marasmus, anorexia nervosa), vitamin B_{12} or folate deficiency	Megaloblastic anemia, hypersegmented neutrophils

Modified from Boxer LA, Blackwood RA: Leukocyte disorders: Quantitative and qualitative disorders of the neutrophil, part I. Pediatr Rev 1996;17:19–28.

TABLE 121-2 -- Acquired Disorders of Myeloid and Stem Cells

Cause	Associated Findings
Acute myelogenous or acute lymphocytic leukemia	Bone marrow replacement with malignant cells
Myelodysplasias	Bone marrow hypoplasia with megaloblastoid red cell precursors, increased numbers of blasts, increased red cell mean cell volume

Paroxysmal nocturnal hemoglobinuria	Absent expression of CD16 on neutrophils, abnormal Ham test
Aplastic anemia	Marked bone marrow hypoplasia
Vitamin B_{12} /folate deficiency	Megaloblastic anemia
Neutropenia in premature infants	Reduced numbers of bone marrow bands and segmented neutrophils
Chronic idiopathic neutropenia	Bone marrow arrest from promyelocytes through segmented neutrophils may occur

TABLE 121-3 -- **Intrinsic Disorders of Proliferation and Maturation of Myeloid and Stem Cells**

Disorder	Mode of Inheritance	Associated Findings	Bone Marrow Findings
Cyclic neutropenia	AD	Periodic oscillation in ANC	Hypoplasia or myeloid maturation arrest, increased number of eosinophils
Severe congenital neutropenia (Kostmann syndrome)	Sporadic occurrence	Profound neutropenia, monocytosis, eosinophilia	Arrest in myeloid maturation at promyelocyte stage
Chronic benign neutropenia	AD, AR, sporadic	Mild neutropenia	Variable pattern, including normal-appearing marrow
Shwachman-Diamond syndrome	AR	Pancreatic insufficiency with fatty replacement and atrophy, anemia, thrombocytopenia, metaphyseal dysostosis	Hypocellularity associated with leukemic transformation
Cartilage-hair hypoplasia	AR	Short-limb dwarfism, fine hair, moderate neutropenia, impaired cellular immunity	Myeloid hypoplasia
Dyskeratosis congenita	X	Nail dystrophy, leukoplakia, reticulated hyperpigmentation of the skin	Marrow hypoplasia
Glycogen storage disease type 1b	AR	Hepatic enlargement, growth retardation, impaired neutrophil motility	Myeloid hypoplasia
Chédiak-Higashi syndrome	AR	Partial albinism, giant granules in myeloid cells, platelet storage pool defect, natural killer cell function impaired, ineffective myelopoiesis	Myeloid hypoplasia
Myelokathexis	AR	Neutrophils have cytoplasmic vacuoles and abnormal nuclei with thin filaments connecting the nuclear lobes	Myeloid hyperplasia
Hyper IgM syndrome	X, AR	Absent IgG, elevated IgM	Maturation arrest at promyelocyte-myelocyte stage

AD = autosomal dominant; AR = autosomal recessive; X = X-linked recessive; ANC = absolute neutrophil count.

From Boxer LA, Blackwood RA: Leukocyte disorders: Quantitative andqualitative disorders of the neutrophil, part 1. Pediatr Rev 1996;17:19–28.

Fever, rash, lymphadenopathy, hepatitis, nephritis, pneumonitis, or aplastic anemia are often associated with hypersensitivity-induced neutropenia. Acute hypersensitivity reactions such as those caused by phenytoin or phenobarbital may last for only a few days if the offending drug is discontinued. Chronic hypersensitivity may last for months to years. Drug-induced neutropenia may occasionally be asymptomatic despite severely reduced numbers of neutrophils and is noted only because of regular monitoring of WBC counts during drug therapy.

Neutropenia complicating the use of anticancer drugs or radiation therapy, especially radiation therapy directed at the pelvis or sternum, is common, secondary to the effects of the cytotoxicity on rapidly replicating cells. A decline in the WBC count typically occurs 7–10 days after administration of the anticancer drug and may persist for 2–3 wk. The neutropenia accompanying both malignancy and following cancer chemotherapy is frequently associated with compromised cellular immunity, thereby predisposing patients to a much greater risk of infection than those disorders associated with isolated neutropenia (Chapter 164).

BONE MARROW REPLACEMENT.

Various acquired disorders may lead to neutropenia accompanied by anemia and thrombocytopenia. The most important among these are hematologic malignancies including leukemia and lymphoma, and metastatic solid tumors such as neuroblastoma, rhabdomyosarcoma, and Ewing's sarcoma that infiltrate the bone marrow and lead to suppression of myelopoiesis. Neutropenia may also accompany myelodysplastic disorders or preleukemic syndromes, which typically are characterized by peripheral cytopenias and macrocytic blood cells associated with impaired production of myeloid precursors.

Splenic enlargement resulting from intrinsic splenic disease, portal

TABLE 121-5 -- **Immune-Mediated, Toxic, and Hypersensitivity-Mediated Neutropenia**

Characteristic	Immunologic Form	Toxic Form	Hypersensitivity Form
Paradigm drugs	Aminopyrine, propylthiouracil, penicillin	Phenothiazine	Phenytoin, phenobarbital
Time to onset	Days to weeks	Weeks to months	Weeks to months
Clinical appearance	Acute, often explosive symptoms	Often asymptomatic or insidious onset	May be associated with fever, rash, ephritis, pneumonitis, or aplastic anemia
Rechallenge	Prompt recurrence with small test dose	Latent period; high doses required	Latent period; high doses required
Laboratory findings	Antibody test results positive	Evidence of direct toxicity to cells	Evidence of metabolite-mediated damage to cells

From Boxer LA: Approach to the patient with leukopenia. In Humes H (editor): Kelley's Textbook of Internal Medicine, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2000, p 1579.

hypertension, or other causes of splenic hyperplasia can lead to neutropenia. The neutropenia often is mild to moderate and accompanied by a corresponding degree of thrombocytopenia and anemia, and may be corrected by successfully treating the

underlying disease. The reduced neutrophil survival corresponds to the size of the spleen, and the extent of the neutropenia is inversely proportional to bone marrow compensatory mechanisms. In selected cases, splenectomy may be necessary to restore the neutrophil count to normal, but this predisposes patients to infections by encapsulated bacterial organisms.

IMMUNE NEUTROPENIA.

Immune neutropenias are associated with the presence of circulating antineutrophil antibodies, which may mediate neutrophil destruction by complement-mediated lysis or splenic phagocytosis of opsonized neutrophils.

Alloimmune Neonatal Neutropenia (ANN). This form of neonatal neutropenia occurs after transplacental transfer of maternal alloantibodies directed against antigens on the infant's neutrophils, analogous to Rh hemolytic disease. Prenatal sensitization induces maternal IgG antibodies to neutrophil antigens on fetal cells. The antibodies are usually complement-activating and are frequently directed to neutrophil-specific antigens. The pathogenesis of ANN usually involves phagocytosis of antibody-coated neutrophils by splenic macrophages. Symptomatic infants may present with delayed separation of the umbilical cord, mild skin infections, fever, and pneumonia within the first 2 wk of life; these resolve with antibiotic therapy. The neutropenia is often severe and associated with fever and infections due to the usual microbes that cause neonatal disease. By 7 wk of age, the infant's neutrophil count usually returns to normal, reflecting the duration of survival of maternal antibody in the infant's circulation. Treatment consists of supportive care and appropriate antibiotics for clinical infections.

Autoimmune Neutropenia. Autoimmune neutropenia is analogous to autoimmune hemolytic anemia and thrombocytopenia. Antibodies causing neutropenia have been detected in patients who have no other signs of autoimmune disease, in patients who have additional antibodies against red blood cells and/or platelets, and in patients who have a connective tissue disorder. Autoimmune neutropenia is distinguished from other forms of neutropenia only by the demonstration of antineutrophil antibodies rather than by abnormal bone marrow histology. Autoimmune neutropenia frequently occurs in children with congenital and acquired forms of immune deficiencies, including dysgammaglobulinemia.

Autoimmune Neutropenia of Infancy (ANI). This benign condition has been diagnosed more frequently as reliable techniques for detection of antineutrophil antibodies have become more widely available. The exact incidence of ANI remains unknown, but because of its benign nature, the disorder may be more common than currently appreciated. In one study, ANI occurred with an annual incidence of approximately 1/100,000 among children between infancy and 10 yr. All patients recognized as having ANI have severe neutropenia on presentation, with an ANC usually less than 500/µL, but the total WBC count is always within normal limits. Monocytosis or

eosinophilia may occur but does not seem to affect the rate of infection. The age at diagnosis is between 5 and 15 mo, with a female:male ratio of 6:4. None of the affected children has evidence of other autoimmune diseases. Children with ANI present with minor infections such as otitis media, gingivitis, respiratory tract infections, gastroenteritis, and cellulitis. The diagnosis often is considered only after the blood count reveals neutropenia. Occasionally, children may present with more severe infections including pneumonia, sepsis, or abscesses. Longitudinal studies of infants with ANI demonstrate a median duration of disease of approximately 7 to 24 months. The diagnosis is established by the presence of antineutrophil antibodies in serum. Treatment with recombinant human granulocyte-colony stimulating factor (rhG-CSF) may be useful in providing temporary remission in infants with severe infections or requiring surgical intervention.

Neonatal Autoimmune Neutropenia. Mothers with autoimmune disease may give birth to infants who develop transient neutropenia. The duration of the neutropenia depends on the time required for the infant to clear the maternally transferred circulating IgG antibody. It persists in most cases for a few weeks to a few months. Neonates almost always remain asymptomatic.

INEFFECTIVE MYELOPOIESIS.

Ineffective myelopoiesis may be acquired as a result of vitamin B_{12} deficiency, which may result from resection of the distal ileum, or folic acid deficiency. Megaloblastic pancytopenia also can result from extended use of antibiotics such as trimethoprim-sulfamethoxazole, which inhibit folic acid metabolism, and from the use of phenytoin, which may impair folate absorption in the small intestine. Neutropenia also occurs with starvation and marasmus in infants, anorexia nervosa, and occasionally among patients receiving prolonged parenteral feedings.

INTRINSIC DISORDERS OF PROLIFERATION AND MATURATION OF MYELOID STEM CELLS.

The isolated disorders of proliferation and maturation of myeloid stem cells are rare. These patients frequently benefit from rhG-CSF therapy. Congenital disorders that have severe neutropenia as a clinical feature include the severe combined immunodeficiencies (Chapter 116), hyper IgM (Chapter 116), and common variable immunodeficiency (Chapter 114).

Cyclic Neutropenia. Cyclic neutropenia, a congenital granulopoietic disorder, is inherited in an autosomal dominant manner in some patients (see Table 121–3). It is characterized by regular, periodic oscillation in the number of peripheral neutrophils from normal to neutropenic values with a mean oscillatory period of 21 ± 3 days. During the neutropenic phase, most patients suffer from oral ulcers, fever, stomatitis, or pharyngitis, occasionally associated with lymph node enlargement. Serious infections occur occasionally and may lead to pneumonia, chronic periodontitis, and recurrent ulcerations of the oral, vaginal, and rectal mucosa. Sepsis, notably with *Clostridium perfringens,* and death may occur. Cyclic neutropenia arises from a regulatory abnormality involving early hematopoietic precursor cells and is associated with mutations in the neutrophil elastase gene. Many patients live for a considerable number of years, with some actually experiencing abatement of symptoms as they age. The cycles tend to become less noticeable in older patients, and the hematologic picture often begins to resemble that of chronic neutropenia.

Severe Congenital Neutropenia. Severe congenital neutropenia, or **Kostmann disease,** is characterized by an arrest in myeloid maturation at the promyelocyte stage of the bone marrow, resulting in an ANC of less than 200/µL (see Table 121–3). This disorder occurs sporadically or as an autosomal dominant or recessive disorder. Patients typically show monocytosis and eosinophilia and suffer from recurrent, severe pyogenic infections, especially of the skin, mouth, and rectum. Anemia associated with chronic inflammatory disease is often present. Approximately 10% of patients develop acute myelogenous leukemia or myelodysplasia associated with monosomy 7. The neutropenia in the majority of patients is associated with mutations in the neutrophil elastase gene, which in turn leads to accelerated apoptosis of bone marrow myeloid cells. Before the use of rhG-CSF, two thirds of these patients died of fatal infections before reaching adolescence.

Shwachman-Diamond Syndrome. Shwachman-Diamond syndrome is an autosomal recessive disorder characterized by digestive abnormalities and abnormally low WBC counts (see Table 121–3). The initial symptoms are usually diarrhea and failure to thrive because of malabsorption, which develops in almost all infants by 4 mo of age. Growth failure and metaphyseal chondrodysplasia associated with dwarfism are especially prominent during the 1st and 2nd yr of life. Puberty is often delayed. Some patients have respiratory problems with pneumonia and frequent otitis media, as well as eczema. Virtually all patients with Shwachman-Diamond syndrome have neutropenia, with the ANC periodically less than 1,000/µL. Some children have been reported to have a chemotactic defect that may contribute to the increased susceptibility to pyogenic infection. The illness may progress to bone marrow hypoplasia leading to moderate thrombocytopenia and anemia. Myelodysplasia and acute myelogenous leukemia associated with monosomy 7 have also been reported in this syndrome. The neutropenia responds to treatment with rhG-CSF.

Cartilage-Hair Hypoplasia. Cartilage-hair hypoplasia is a multisystem autosomal recessive disorder characterized by short limbs and short stature resulting from abnormal development of long bone cartilage (Chapter 116). The major symptoms include abnormalities of the spine, hyperextensible fingers, and very fine, thin hair, eyebrows, and eyelashes (see Table 121–3). Cartilage-hair hypoplasia is associated with decreased cell-mediated immunity, neutropenia, macrocytic anemia, and increased rates of malignancy. Bone marrow transplantation has restored cellular immunity and corrected the neutropenia.

Glycogen Storage Disease Type Ib. Recurrent infections with neutropenia are a distinctive feature of glycogen storage disease (GSD) type Ib (see Table 121–3). Both classic von Gierke glycogen storage disease (GSDIa) and GSDIb cause massive enlargement of liver and severe growth retardation. In contrast to GSDIa, glucose-6-phosphatase activity is present by in vitro assays but glucose is not liberated from glucose-6-phosphate in vivo with GSDIb. In the liver, glucose-6-phosphatase requires two microsomal membrane components: a specific transfer system, glucose-6-phosphatase translocase, which shuttles glucose-6-phosphate from the cytoplasm to the lumen of the endoplasmic reticulum where it is hydrolyzed by a second enzyme, glucose-6-phosphalase, into glucose and inorganic phosphate. Neutrophils also appear to have a defective transport system resulting in defective neutrophil motility that is associated with the neutropenia. Patients with GSDIb with severe neutropenia are predisposed to recurrent bacterial infections. Treatment with rhG-CSF can correct the neutropenia.

Severe Chronic Neutropenia. Acquired idiopathic chronic symptomatic neutropenia is characterized by onset of neutropenia after 2 yr of age, and more frequently among adults. It is characterized by neutrophil counts that are occasionally less than 500/µL. Patients with an ANC persistently less than 500/µL are afflicted with recurrent pyogenic infections involving the skin, mucous membranes, lungs, and lymph nodes. Bone marrow examination reveals variable patterns of myeloid formation with arrest generally occurring between the myelocyte and band forms (see Table 121–2).

Some forms of chronic neutropenia, such as myelokathexis, arise from an impaired release of neutrophils from the bone marrow into the peripheral blood. Children with myelokathexis have morphologic abnormalities of the neutrophils, with the cells showing cytoplasmic vacuoles of thin strands connecting

the nuclear lobes. In some cases, these patients also have cellular immune defects and are predisposed to recurrent bacterial infections (see Table 121–3).

Chronic Benign Neutropenia. In contrast to severe congenital neutropenia, chronic benign neutropenia of childhood represents a common group of disorders characterized by mild to moderate neutropenia that does not lead to an increased risk of pyogenic infections. Spontaneous remissions have often been reported, although these may represent misdiagnosis of autoimmune neutropenia of infancy, in which remissions occur commonly during childhood. Chronic benign neutropenia may be inherited in either a dominant or recessive form. An autosomal recessive form of benign neutropenia is encountered in Yemenite Jews. Because of the relatively low risk of serious infection, patients should be not subjected to the potential toxic effects of prolonged administration of corticosteroids, splenectomy, or cytotoxic therapy (see Table 121–3).

Clinical Manifestations.

Individuals with neutrophil counts below 500/µL are at substantial risk for developing infections, primarily from their endogenous flora as well as from nosocomial organisms. Some patients with isolated chronic neutropenia with an ANC below 200/µL may not experience many serious infections, probably because the remainder of the immune system remains intact. In contrast, children whose neutropenia is secondary to acquired disorders of production such as with cytotoxic therapy, immunosuppressive drugs, or radiation therapy, particularly in conjunction with malignancies, are likely to develop serious bacterial infections because many arms of the immune system are markedly compromised.

Leukopenia associated with neutropenia, in addition to monocytopenia and lymphocytopenia, is often more serious than neutropenia alone. The integrity of skin and mucous membranes, the vascular supply to tissues, and the nutritional status of

patients influence the risk of infection.

The clinical presentation in most patients with profound neutropenia is fever exceeding 101°F, cellulitis, and furunculosis. Stomatitis, gingivitis, perirectal inflammation, colitis, sinusitis, and otitis media are frequent accompaniments of profound neutropenia in children. Other clinical manifestations of profound neutropenia include hepatic abscesses, recurrent pneumonias, and septicemia. In contrast, isolated neutropenia does not heighten a patient's susceptibility to fungal, parasitic, or viral infections or to bacterial meningitis.

The most common pathogens isolated from neutropenic patients are *Staphylococcus aureus* and gram-negative bacteria. The usual signs and symptoms of local infection and inflammation such as exudate, fluctuance, and regional lymphadenopathy are generally less in the presence of neutropenia because of the inability to form pus. However, neutropenic patients can experience pain at sites of inflammation.

Laboratory Findings.

Isolated absolute neutropenia has a limited number of causes (see Tables 121–1, 121–2, and 121–3). The duration and severity of the neutropenia greatly influence the extent of laboratory evaluation. Patients with chronic neutropenia since infancy and a history of recurrent fevers and chronic gingivitis should have WBC counts and differential counts determined three times weekly for 6 wk to evaluate the periodicity suggestive of cyclic neutropenia. Bone marrow aspiration and biopsy should be performed on selected patients to assess cellularity. Additional marrow studies such as cytogenetic analysis and special stains for detecting leukemia and other malignant disorders should be obtained for patients with suspected intrinsic defects in the myeloid cells or the progenitors, and for patients with suspected malignancy. Selection of further laboratory tests is determined by the duration and severity of the neutropenia and the associated findings on physical examination (see Fig. 121–1).

Treatment.

The management of acquired transient neutropenia associated with malignancies, myelosuppressive chemotherapy, or immunosuppressive chemotherapy differs from that of congenital or chronic forms of neutropenia. In the former situation, infections sometimes are heralded only by fever, and sepsis is a major cause of death. Early recognition and treatment of infections may be lifesaving (Chapter 164).

Therapy of severe chronic neutropenia is dictated by the clinical manifestations. Patients with benign neutropenia and no evidence of repeated bacterial infections or chronic gingivitis require no specific therapy. Superficial infections in children with mild to moderate neutropenia may be treated with appropriate oral antibiotics. However, in patients who have life-threatening infections, broad-spectrum intravenous antibiotics should be started promptly.

Effective treatment of severe chronic neutropenia including severe congenital neutropenia, chronic symptomatic idiopathic neutropenia, and cyclic neutropenia is now possible. A randomized controlled trial of these patients treated with subcutaneously administered rhG-CSF at doses ranging from 3.4 to 11.50?µg/kg/24?hr led to dramatic increases in neutrophil counts, resulting in marked attenuation of infection and inflammation. rhG-CSF has also been successfully administered to some patients with drug-induced neutropenia whose neutrophil count failed to increase after cessation of the offending drug. The long-term effects of rhG-CSF therapy are unknown but include a propensity for the development of moderate splenomegaly, thrombocytopenia, and, occasionally, vasculitis. Autoimmune neutropenia may be responsive to intermittent corticosteroids, especially if it is part of an underlying disease process such as systemic lupus erythematosus. Although this remains unproved by controlled studies, use of rhG-CSF has benefited some patients who have immune or drug-induced neutropenias.

Those patients with severe congenital neutropenia or Shwachman-Diamond syndrome who develop myelodysplasia or acute myelogenous leukemia respond only to allogeneic bone marrow transplantation. Chemotherapy is ineffective.

LYMPHOPENIA

Lymphocytes account for about 30% of the circulating WBCs in a newborn. The proportion of lymphocytes then increases rapidly within the 1st mo, reaching an average of 60% by 2 yr of age. The normal lymphocyte count in children younger than 2 yr is 3,000–9,500/µL and in adults is 1,000–4,800/µL. At 6 yr of age, the lower limit of normal is 1,500/µL.

Almost 65% of blood T lymphocytes are CD4 (helper) T lymphocytes. Most patients with lymphocytopenia have a reduction in the absolute number of T lymphocytes, particularly in the number of CD4 T lymphocytes. The average number of CD4 T lymphocytes in adult blood is 1,100/µL (range, 300–1,300/µL), and the average number of CD8 (suppressor) T lymphocytes is 600/µL (range, 100–900/µL), with the normal CD4:CD8 ratio of 1.8–2.0.

Lymphocytopenia by itself usually causes no symptoms and is often detected in the evaluation of other illnesses, particularly recurrent viral, fungal, and parasitic infections. Lymphocyte subpopulations can be measured by multiparameter flow cytometry, which uses the pattern of antigen expression to classify and characterize these cells.

INHERITED CAUSES OF LYMPHOCYTOPENIA.

Inherited immunodeficiency disorders may have a quantitative or qualitative stem cell abnormality resulting in ineffective lymphocytopoiesis (Box 121–1). Other disorders such as Wiskott-Aldrich syndrome may have associated lymphocytopenia arising from accelerated destruction of T cells. A similar mechanism is present in patients with adenosine deaminase deficiency and purine nucleoside phosphorylase deficiency.

Box 121-1. Causes of Lymphocytopenia

ACQUIRED CAUSES

- Infectious diseases
  - AIDS
  - Viral hepatitis
  - Influenza
  - Tuberculosis
  - Typhoid fever
  - Sepsis
- Iatrogenic
  - Immunosuppressive therapy
  - Corticosteroids
  - High-dose PUVA therapy
  - Cytotoxic chemotherapy
  - Radiation
  - Thoracic duct drainage
- Systemic and other diseases
  - Systemic lupus erythematosus
  - Myasthenia gravis
  - Hodgkin disease
  - Protein-losing enteropathy
  - Renal failure
  - Sarcoidosis
  - Thermal injury
  - Aplastic anemia
- Dietary deficiency

  - Thermal injury
  - Aplastic anemia
- Dietary deficiency

  - Dietary deficiency associated with ethanol abuse

INHERITED CAUSES

- Aplasia of lymphopoietic stem cells
- Severe combined immunodeficiency associated with defect in IL-2 receptor ?-chain, deficiency of ADA or PNP, or unknown
- Ataxia-telangiectasia
- Wiskott-Aldrich syndrome
- Immunodeficiency with thymoma
- Cartilage-hair hypoplasia
- Idiopathic CD4 T lymphocytopenia

ADA = adenosine deaminase; PNP = purine nucleoside phosphorylase; IL-2 = interleukin-2; PUVA = psoralen and ultraviolet A irradiation. From Boxer LA: Approach to the patient with leukopenia. In Humes HD (editor): *Kelley's Textbook of Internal Medicine*, 4th ed. Philadelphia, Lippincott Williams & Wilkins, 2000, p 1580.

ACQUIRED LYMPHOCYTOPENIA.

Acquired lymphocytopenia is the result of depletion of blood lymphocytes that is not secondary to inherited diseases. AIDS is the most common infectious disease associated with lymphocytopenia, which results from destruction of CD4 T cells infected with HIV-1 or HIV-2. Other viral and bacterial diseases may be associated with lymphocytopenia. In some instances of acute viremia with other viral infections, lymphocytes may undergo accelerated destruction from intracellular viral replication, be trapped in the spleen or nodes, or migrate to the respiratory tract.

Iatrogenic lymphocytopenia is caused by cytotoxic chemotherapy, radiation therapy, and long-term administration of antilymphocyte globulin. Long-term treatment of psoriasis with psoralen and ultraviolet irradiation may destroy T lymphocytes.

Corticosteroids can cause lymphopenia through increased cell destruction. Systemic autoimmune diseases such as systemic lupus erythematosus are associated with lymphocytopenia. Other conditions such as protein-losing enteropathy and aberrant or surgical drainage of the thoracic duct are associated with lymphocyte depletion, leading to lymphocytopenia.

Chapter 122 - Leukocytosis

Laurence A. Boxer

Leukocytosis is an elevation in the total leukocyte, or white blood cell (WBC), count that is two standard deviations above the mean count for a particular age (Chapter 710). The various causes of leukocytosis are categorized by the class of WBCs that is elevated and whether the leukocytosis is acute, chronic, or lifelong.

A WBC count exceeding 50,000/µL is termed a **leukemoid reaction** because of the similarity to features of leukemia. Leukemoid reactions are usually neutrophilic and are most frequently associated with septicemia and severe bacterial infections including shigellosis, salmonellosis, and meningococcemia. Infection in children with leukocyte adhesion deficiency results in WBC counts approaching or exceeding 100,000/µL.

A significant proportion of greater than 5% of immature to mature neutrophil cells is termed a **shift to the left** and indicates rapid release of cells from the bone marrow. This may result in increased circulating band forms, which usually constitute 1–5% of circulating neutrophilic cells, or metamyelocytes and myelocytes, which are not usually found in the peripheral circulation. Higher degrees of shift to the left with more immature neutrophil precursors are indicative of serious bacterial infections but may also be encountered with trauma, burns, surgery, and acute hemolysis or hemorrhage.

Neutrophilia.

Neutrophilia is an increase in the total number of blood neutrophils, which for older children and adults is greater than 8,000/µL. During the first day of life, the upper limit of the normal neutrophil count ranges from 7,000 to 12,000/µL. In the 1st mo of life the neutrophil count ranges from 1,800 to 5,400/µL, and by 1 yr of age, the range is 1,500–8,500/µL.

An increase in circulating neutrophils is a result of a disturbance of the normal equilibrium involving bone marrow neutrophil production, movement out of the marrow compartments into the circulation, and neutrophil destruction. Neutrophilia may arise either alone or in combination with enhanced mobilization into the **circulating pool** from either the bone marrow storage compartment or the peripheral

blood **marginating pool**, by impaired neutrophil egress into tissues, or after expansion of the circulating neutrophil pool secondary to increased progenitor cell proliferation and terminal differentiation through the myeloid series. Myelocytes are not released to the blood except under extreme circumstances.

ACUTE ACQUIRED NEUTROPHILIA.

Neutrophilia is usually an acquired disorder and is a common finding with inflammation, infection, injury, and stress. Acute or chronic bacterial infections, trauma, and surgery are among the most common causes encountered in clinical practice. Neutrophilia is often associated with sickle cell disease, some chronic hemolytic anemias, heatstroke, burns, and diabetic ketoacidosis. Drugs commonly associated with neutrophilia include epinephrine, corticosteroids, and recombinant growth factors such as recombinant human granulocyte colony-stimulating factor (rhG-CSF) and recombinant human granulocyte-macrophage colony stimulating factor (rhGM-CSF). Epinephrine causes

release into the circulation of a sequestered pool of neutrophils that normally marginate along the vascular endothelium. Corticosteroids accelerate the release of neutrophils and bands from a large storage pool within the bone marrow and impair the migration of neutrophils from the circulation into tissues. Acute neutrophilia in response to inflammation and infections occurs because of release of neutrophils from the marrow storage pool. The post-mitotic marrow neutrophil pools are approximately 10 times the sizes of the blood neutrophil pool, and about half of these cells are bands and segmented neutrophils. In neutrophil production disorders, such as those associated with malignancies and cancer chemotherapy, the size of this pool may be reduced and the capacity to develop neutrophilia remains impaired. Exposure of blood to foreign substances such as hemodialysis membrane activates the complement system and causes transient neutropenia followed by neutrophilia because of release of bone marrow neutrophils. The colony-stimulating factors, G-CSF and GM-CSF, cause acute and chronic neutrophilia by mobilizing cells from the marrow reserves and by stimulating neutrophil production.

CHRONIC ACQUIRED NEUTROPHILIA.

Chronic neutrophilia is usually associated with continued stimulation of neutrophil production resulting from persistent inflammatory reactions or chronic infections such as tuberculosis, vasculitis, postsplenectomy states, Hodgkin disease, chronic myelogenous leukemia, chronic blood loss, and prolonged administration of corticosteroids. Chronic neutrophilia can arise following expansion of cell production secondary to stimulation of cell divisions within the mitotic precursor pool, which consists of promyelocytes and myelocytes (Fig. 122–1). Subsequently, the size of the post-mitotic pool increases. These changes lead to an increase in the marrow reserve pool, which can be readily mobilized for release of neutrophils into the circulation. The neutrophil production rate can increase greatly in response to exogenously administered hemopoietic growth factors such as rhG-CSF, with a maximum response taking at least 1 wk to develop.

Figure 122-1 Cytokine control of the phagocyte production and activation by release of endotoxin during infection. Both endothelial cells and fibroblasts release substantial quantities of both granulocyte macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) in response to tumor necrosis factor (TNF) and interleukin-1 (IL-1). Both TNF and IL-1 are released from endotoxin-activated monocytes and antigen-activated T-lymphocytes. Stem cell factor (SCF), interleukin-3 (IL-3), GM-CSF, and interleukin-6 (IL-6) each influence the growth and differentiation of multilineage progenitor cells known as colony forming units (CFU)-granulocytes, eosinophils, monocytes, megakaryocytes (CFU_{GEMM})-to the committed colony forming unit macrophage (CFU_{M}), CFU eosinophil (CFU_{eo}), or CFU granulocyte (CFU_{G}). Platelet production can also be augmented by expansion of CFU megakaryocyte (CFU_{meg}). Factors that serve as growth and differentiation factors for a specific lineage also act as activation factors for the terminally differentiated forms of the same lineage. Macrophage-colony stimulating factor (M-CSF) enhances antibody-mediated cytotoxicity and phagocyte functions of monocytes. G-CSF promotes neutrophil bactericidal capacity, and interleukin-5 (IL-5) activates eosinophil function. Within hours of an infection, cytokine primed neutrophils move to the invasion site from the circulation under the influence of interleukin-8 (IL-8), which is released from endothelial cells and fibroblasts.

LIFELONG NEUTROPHILIA.

Congenital asplenia is associated with lifelong neutrophilia. Uncommon genetic disorders that present with neutrophilia include leukocyte adhesion deficiency, familial myeloproliferative disease, Down syndrome, and Rac-2 mutation. In an autosomal dominant form of hereditary neutrophilia, patients maintain an absolute neutrophil count between 1,400 and 150,000/µL that is associated with hepatosplenomegaly, an increased alkaline phosphatase level, and Gaucher-type histiocytes in the bone marrow.

Evaluation of persistent neutrophilia requires a careful history, physical examination, and laboratory studies to search for infectious, inflammatory, and neoplastic conditions. The leukocyte alkaline phosphatase cytochemical stain of circulating neutrophils is useful to differentiate chronic myelogenous leukemia, in which the level is uniformly near zero, from reactive or secondary neutrophilia, in which normal to elevated levels are found.

Monocytosis.

The average absolute blood monocyte count varies with age, which must be considered in the assessment of monocytosis. Given the role of monocytes in antigen presentation and cytokine secretion and as effectors of ingestion of invading organisms, it is not surprising that many clinical disorders give rise to monocytosis (Box 122–1). Most commonly, monocytosis occurs in patients recovering from myelosuppressive chemotherapy and is a harbinger of the return of the neutrophil count to normal. Monocytosis is often a sign of an acute bacterial, viral, protozoal, or rickettsial infection, and also occurs in some forms of chronic neutropenia and postsplenectomy states. Chronic inflammatory conditions can stimulate sustained monocytosis, including preleukemia, chronic myelogenous leukemia, lymphomas,

and occasionally Hodgkin disease.

Lymphocytosis.

The most common cause of lymphocytosis is an acute viral illness. Lymphocytosis is a normal response to most viral infections because the majority of circulating lymphocytes are T cells. In infectious mononucleosis, the B cells are infected with the Epstein-Barr virus and the T cells react to the viral antigens present in the B cells, resulting in **atypical lymphocytes** with the typical large, vacuolated morphology. Other viral diseases classically associated with lymphocytosis are cytomegalovirus and viral hepatitis. Chronic bacterial infections such as tuberculosis and brucellosis may lead to a sustained lymphocytosis. Pertussis is accompanied by lymphocytosis in approximately 25% of infants infected before 6 mo of age. Thyrotoxicosis and Addison disease are endocrine disorders associated with lymphocytosis. Persistent or profound lymphocytosis suggests acute lymphocytic leukemia.

Section 4 - *The Complement System*

Richard B. Johnston Jr.

Chapter 123 - The Complement System

Complement was originally defined as the nonspecific, heat-labile complementary principle required with specific antibody to lyse bacteria. The first four components were numbered in the order of their discovery and are now termed the classical pathway. Unfortunately for subsequent generations of students and physicians, the components fix to the immune complex in a different order, C1423. Once beyond this regrettable beginning, complement emerges as a logical, exquisitely balanced, and highly influential system that is fundamental to the clinical expression of inflammatory disease.

The complement system can now be broadly conceptualized as the **classical, mannose-binding lectin (MBL), and alternative pathways**, which interact and depend on each other for their full activity; the **membrane attack complex (C5b6789)**, formed from activity of any pathway; the eight serum and four membrane regulatory proteins well defined to date; a

serosal regulatory protein; and seven fully defined cell membrane receptors that bind complement components or fragments (Table 123–1). The 24 serum components and regulators together compose about 15% of the globulin fraction of serum. The normal concentrations of serum complement components vary by age (Chapter 710); newborn infants have mild to moderate deficiencies of all plasma components of the complement system.

After C1423, complement nomenclature is logical and consists of only a few rules. Fragments of components resulting from cleavage by other components acting as enzymes are assigned lowercase letters (a, b, c, d, or e); with the exception of C2 fragments, the smaller piece that is released into surrounding fluids is assigned the lowercase letter a, and the major part of the molecule, bound to other components or to some part of the immune complex, is assigned letter b—for example, C3a and

C3b. Components of the alternative pathway, B and D, have been assigned uppercase letters, as have the control proteins I and H, which downregulate both pathways. C3, and especially its major fragment C3b, is a component of both the classical and alternative pathways.

Complement is a system of interacting proteins. The biologic functions of the system depend on the interactions of individual components, which occur in sequential, cascade fashion. Activation of each component, except the first, depends on activation of the prior component or components in the sequence. Interaction occurs along three pathways (Fig. 123–1): the classical pathway, in the order antigen–antibody–C142356789; the MBL pathway, in the order microbial mannan–MBL/MBL-associated proteases 1 and 2–C42356789; and the alternative pathway, in the order activator–C3bBD–C356789. Antibody accelerates the rate of activation of the alternative pathway, but activation can occur on appropriate surfaces in the absence of

antibody. The classical and the alternative pathways interact with each other through the ability of both to activate C3.

Activation of the early-acting components of complement (C1423) results in the generation of a series of active enzymes, C1, C42, and C423, on the surface of the immune complex or underlying cell. These enzymes cleave and activate the next component in the sequence. In contrast, the interaction among C5b, C6, C7, C8, and

C9 is nonenzymatic and depends on changes in molecular configuration.

Classical Pathway.

The classical pathway sequence begins with fixation of C1, by way of C1q, to the Fc, non–antigen-binding part of the antibody molecule after antigen-antibody interaction. The C1 tricomplex changes configuration and the C1s subcomponent becomes an active enzyme, C1 esterase.

C-reactive protein (CRP), which reacts with C carbohydrate from microorganisms and is increased in certain inflammatory states, can substitute for antibody in the fixation of C1q and initiate reaction of the entire sequence in the absence of antibody. Other agents that can activate C1 directly, without a requirement for antibody, include certain bacteria, *Mycoplasma,* RNA viruses, uric acid crystals, the lipid A component of bacterial endotoxin, and the products of tissue damage such as apoptotic blebs and mitochondrial membranes.

Mannose-Binding Lectin Pathway.

MBL is a member of the collectin family of carbohydrate-binding proteins that are believed to play an important part in innate, nonspecific immunity; its structure is homologous to that of C1q. MBL, in association with two **MBL-associated serine proteases (MASPs),** can bind to mannan on bacterial and fungal surfaces and function like C1s to cleave C4 and C2 and activate the complement cascade. A kinin-like peptide split from C2 can induce vascular permeability and edema through direct action on postcapillary venules. The peptide C4a has weak anaphylatoxin activity; it reacts with mast cells to release the chemical mediators of immediate hypersensitivity, including histamine. C3a and C5a, released later in the sequence, are more potent anaphylatoxins, and C5a is also an important chemotactic factor. Fixation of C4b to the complex permits it to adhere to neutrophils, macrophages, B cells, dendritic cells, and erythrocytes.

Cleavage of C3 and generation of C3b is the next step in the sequence. The C3 concentration is the highest of any component, and its activation is the most crucial step in terms of biologic activity. Cleavage of C3 can be achieved through the **C3 convertase** of the classical pathway, C142, or of the alternative pathway, C3bBb. Once fixed to the complex, C3b permits adherence of the antigen-antibody complex to cells with receptors for C3b **(complement receptor 1 [CR1]),** including B lymphocytes, erythrocytes, and phagocytic cells (neutrophils, monocytes, and macrophages), leading, in the last case, to phagocytosis. Phagocytosis of most microorganisms in vitro, especially by neutrophils, is inefficient without binding of C3 to the microorganism. The severe pyogenic infections that commonly occur in C3-deficient patients indicate that phagocytosis is also inefficient in vivo without C3. The biologic activity of C3b is controlled by cleavage by **factor I (C3b inactivator)** to iC3b, which promotes phagocytosis on binding to the **iC3b receptor (CR3)** on phagocytes. Further degradation of iC3b by I and proteases yields C3dg, then C3d; C3d binds to CR2 on B lymphocytes and thereby serves as a co-stimulator of antigen-induced B-cell activation.

Alternative Pathway.

The alternative pathway can be activated by C3b generated through classical pathway activity or through neutrophil or clotting system proteases. It can also be activated by a form of C3 created by low-grade, spontaneous reaction of native C3 with a molecule of water, a “tickover” that occurs constantly in plasma. Once formed, C3b or the hydrolyzed C3 can bind to any nearby cell or to factor B. Factor B attached to C3b in

Figure 123-1 Sequence of activation of the components of the classical/MBL pathway of complement and interaction with the alternative pathway. Activation of C3 is the functionally essential target. (Ag = antigen [bacterium, virus, tumor cell, or erythrocyte]; Ab = antibody [IgG or IgM class only]; C-CRP = C carbohydrate-C-reactive protein; B,D,I,H = factors B, D, I, and H; C4-bp = C4-binding protein; MBL = mannose-binding lectin; MASPs = MBL-associated serine proteases.) The multiple sites at which inhibitory regulator proteins act are indicated by asterisks, emphasizing the delicate balance between action and control in this system that is required for host defense yet capable of mediating profound damage to host tissues.

the plasma or on a surface can be cleaved to Bb by D, which exists as an active proteolytic enzyme. The complex C3bBb becomes an efficient C3 convertase, which generates more C3b through an “amplification loop.” P can bind to C3bBb, increasing stability of the enzyme and protecting it from inactivation by factors I and H, which modulate the loop and the pathway.

Certain “activating surfaces” promote alternative pathway activation if C3b is fixed to them—for example, bacterial teichoic acid or endotoxin—by protecting the C3bBb enzyme complex from the control otherwise exercised by factors I and H. Rabbit red blood cell membrane is such a surface, which serves as the basis for an assay of serum alternative pathway activity. Endotoxin may alter normally “nonactivating” cell surfaces in vivo so that C3bBb is relatively protected from inactivation, which may partially explain the activation of complement in patients with gram-negative bacteremia. Sialic acid on the surface of microorganisms or cells prevents formation of an effective alternative pathway C3 convertase by promoting activity of I and H. In any case, significant activation of C3 can occur through the alternative pathway, and the resultant biologic activities are qualitatively the same as those achieved through activation by C142 (see Fig. 123–1).

Membrane Attack Complex.

The sequence leading to cytolysis begins with the attachment of C5b to the C5-activating enzyme from the classical pathway, C4b2a3b, or from the alternative pathway, C3bBb3b. C6 is bound to C5b without being cleaved, stabilizing the activated C5b fragment. The C5b6 complex then dissociates from C423 and reacts with C7. C5b67 complexes must attach promptly to the membrane of the parent or a bystander cell or they lose their activity. Next, C8 binds, and the C5b678 complex then promotes the addition of multiple C9 molecules. The C9 polymer of at least

three to six molecules forms a transmembrane channel, and lysis ensues.

Control Mechanisms.

Without control mechanisms, acting at multiple points, there would be no effective complement system, and unbridled consumption of components would generate severe, potentially lethal damage to the host. At the first step, C1 inhibitor (C1 INH) inhibits C1r and C1s enzymatic activity and, thus, the cleavage of C4 and C2. Activated C2 has a short half-life, and this relative instability limits the effective life of C42 and C423. The alternative pathway enzyme that activates C3, C3bBb, also has a short half-life, though it can be prolonged by the binding of **properdin (P)** to the enzyme complex. Serum contains the protein “anaphylatoxin inactivator,” an enzyme that cleaves the N-terminus arginine from C4a, C3a, and C5a, thereby markedly reducing their biologic activity. Factor I inactivates C4b and C3b; factor H accelerates inactivation of C3b by I, and an analogous factor, C4-binding protein (C4-bp), accelerates C4b cleavage by I. Three protein constituents of cell membranes, CR1, membrane cofactor protein, and decay-accelerating factor (DAF), promote the disruption of C3 and C5 convertases assembled on those membranes. Other cell membrane–associated proteins (CD59 being the best studied) can bind C8 or both C8 and C9, thereby interfering with insertion of the membrane attack complex (C5b6789). Certain serum proteins (S protein and clusterin being the best studied) can inhibit attachment of the C5b67 complex to cell membranes, bind C8 or C9 in a full membrane attack complex, or otherwise interfere with the formation or insertion of this complex.

Participation in Host Defense.

Neutralization of virus by antibody can be enhanced with C1 and C4 and further enhanced by the additional fixation of C3b through the classical or alternative

pathway. Complement may, therefore, be particularly important in the early phases of a viral infection when antibody is limited. Antibody and the full complement sequence can also eliminate infectivity of at least some viruses by the production of typical complement “holes,” as seen by electron microscopy. Fixation of C1q can opsonize (promote phagocytosis) through binding to the C1q receptor.

C4a, C3a, and C5a can bind to mast cells and thereby trigger release of histamine and other mediators, leading to vasodilatation and the swelling and redness of inflammation. C5a can induce monocytes to release the cytokines tumor necrosis factor and interleukin-1, which amplify the inflammatory response. C5a is a major chemotactic factor for neutrophils, monocytes, and eosinophils, which can efficiently phagocytize microorganisms opsonized with C3b or cleaved C3b (iC3b). Further inactivation of cell-bound C3b by cleavage to C3d removes its opsonizing activity, but it can still bind to B cells. Fixation of C3b to a target cell can enhance its lysis by NK cells or macrophages.

Insoluble immune complexes can be solubilized if they bind C3b, apparently because C3b disrupts the orderly antigen-antibody lattice. Binding C3b to a complex also allows it to adhere to C3 receptors (CR1) on red blood cells, which then transport the complexes to hepatic and splenic macrophages for removal. This phenomenon may at least partially explain the immune complex disease found in patients who lack C1, C4, C2, or C3.

The complement system serves to link the innate and adaptive immune systems. C4b or C3b coupled to immune complexes promotes their binding to antigen-presenting macrophages, dendritic cells, and B cells. Coupling of antigen to C3d allows binding to CR2 on B cells, which reduces the amount of antigen needed to trigger an antibody response by a factor of up to 10,000.

Neutralization of endotoxin in vitro and protection from its lethal effects in experimental animals require later-acting components of complement, at least through C6. Finally, activation of the entire complement sequence can result in lysis of virus-infected cells, tumor cells, and most types of microorganisms. Bactericidal activity of complement has not appeared to be important to host defense, except for the occurrence of *Neisseria* infections in patients lacking later-acting components of complement (Chapter 124).

Chapter 124 - Disorders of the Complement System

124.1 Evaluation

Testing for total hemolytic complement activity (CH_{50}) effectively screens for most of the diseases of the complement system. A normal result in this assay depends on the ability of all 11 components of the classical pathway and membrane attack complex to interact and lyse antibody-coated erythrocytes. The dilution of serum that lyses 50% of the cells determines the end-point. In congenital deficiencies of C1 through C8, the CH_{50} value is 0 or close to 0; in C9 deficiency, the value is approximately half-normal. Values in the acquired deficiencies vary with the type and severity of the underlying disorder. This assay does not detect deficiencies of the alternative pathway components B or D, or of properdin or mannose-binding lectin (MBL). Deficiency of factor I or H permits consumption of C3, with partial reduction in the CH_{50} value. When clotted blood or serum sits for over about an hour, CH_{50} activity begins to decline, which leads to values that are falsely low, but not zero.

In hereditary angioedema, depression of C4 and C2 during an attack significantly reduces the CH_{50} . Serum concentrations of C4 and C3, and indeed all of the components, can be quantitated using specific antibody. In hereditary angioedema, C4 is characteristically low and C3 normal. Concentrations of C1 inhibitor can be determined with antibody, but a normal result can be anticipated in about 15% of cases. Because C1 acts as an esterase, the specific diagnosis can be made by showing increased capacity of patients' sera to hydrolyze synthetic esters.

Decreased serum concentrations of both C4 and C3 suggest activation of the classical pathway by immune complexes. In contrast, decreased C3 and normal C4 levels suggest activation of the alternative pathway. This difference is particularly useful in distinguishing nephritis secondary to complex deposition from that due to NeF (nephritic factor). In the latter condition and in deficiency of factor I or H, factor B is consumed, and its serum concentration is low. Alternative pathway activity can be measured with a relatively simple and reproducible hemolytic assay that depends on the capacity of rabbit erythrocytes to serve as both an activating (permissive) surface and a target of alternative pathway activity.

A defect of complement function should be considered in any patient with recurrent angioedema, autoimmune disease, chronic nephritis, or partial lipodystrophy, or with recurrent pyogenic infections, disseminated meningococcal or gonococcal infections, or a second episode of bacteremia at any age.

124.2 Primary Deficiencies of Complement Components

Congenital deficiencies of all 11 components of the classical-membrane attack pathway and of factor D of the alternative pathway have been described (Table 124–1).

Most patients with primary **C1q deficiency** have had systemic lupus erythematosus (SLE), an SLE-like syndrome without typical SLE serology, a chronic rash that has shown an underlying vasculitis on biopsy, or membranoproliferative glomerulonephritis (MPGN). Some C1q-deficient children have had serious infections, including septicemia and meningitis.

C1rs deficiency occurs as a complete defect of C1r in association with variable deficiency of C1s, presumably due to the close linkage of the genes for these proteins on chromosome 12. Like individuals with C1q deficiency, patients with **C1r/C1s, C4, C2, or C3 deficiency** have had a high incidence of autoimmune syndromes (see Table 124–1), especially SLE or an SLE-like syndrome in which antinuclear antibody level is not elevated. C4 is encoded by two genes, termed C4A and C4B; complete deficiency of C4A, present in about 1% of the population, also predisposes to SLE though C4 levels are only partially reduced. A few patients with **C5, C6, C7, or C8 deficiency** have had SLE, but recurrent *Neisseria* infections are much more likely to be the major problem in this group. The reason for the concurrence of deficiencies of components of complement and these autoimmune diseases is not entirely clear, but deposition of C3 on autoimmune complexes facilitates their removal from the circulation through binding to complement receptor 1 (CR1) on erythrocytes and transport to the spleen and liver. The early components expedite the clearance of necrotic and apoptotic

C4-binding protein						

B/M = Bacteremia or meningitis; DGI = disseminated gonococcal infection; DV/DLE = dermal vasculitis or typical discoid lupus erythematosus; GN =glomerulonephritis in various forms, often membranoproliferative; HIV = human immunodeficiency virus; M = meningitis; MBL = mannose-binding lectin; other AD = other autoimmune diseases (almost all possible diagnoses have been reported); other pyogenic = serious deep or systemic infection due to, or typically caused by, a pyogenic bacterium (abscess, osteomyelitis, pneumonia, bacteremia other than pneumococcal, meningitis other than meningococcal or pneumococcal, cellulitis, myopericarditis, and peritonitis); SLE = typical systemic lupus erythematosus or an SLE-like syndrome without characteristic serologic findings.

Data from Figueroa JE, Densen P: Infectious diseases associated with complement deficiencies. Clin Microbiol Rev 1991;4:359–95; Ross SC, Densen P: Complement deficiency states and infection: Epidemiology, pathogenesis and consequences of neisserial and other infections in an immune deficiency. Medicine 1984;63:243–73, and other case reports and series.

**A finding was reported as “very common” if it occurred in 50% or more of reported cases, “common” if reported in about 5–50% of cases, and “occasional” if present in one or two cases or <5% of the more frequent deficiencies.*

† Hereditary angioedema is a specific entity not typically associated with infection or autoimmunity.

cells, which are sources of autoantigens. Inefficiency of either or both of these processes might explain the particular predisposition to autoimmune disease in individuals with a defect in the classical pathway.

Several patients with **C2 deficiency** have had repeated life-threatening septicemic illnesses, most commonly due to pneumococci. Most have not had problems with increased susceptibility to infection, presumably because of the protective function of the alternative pathway. The genes for C2, factor B, and C4 are situated close to each other on chromosome 6, and a partial depression of factor B levels can occur in conjunction with C2 deficiency. Persons with a deficiency of both proteins may be at particular risk.

Because C3 can be activated by C142 or by the alternative pathway, a defect in the function of either pathway can be compensated for, at least to some extent. Without C3, however, the chemotactic fragment from C5 (C5a) is not generated, and opsonization of bacteria is inefficient. Some organisms must be well opsonized in order to be cleared, and genetic **C3 deficiency** has been associated with recurrent, severe pyogenic infections due to pneumococci and meningococci.

More than half of the individuals reported to have congenital **C5, C6, C7, or C8 deficiency** have had meningococcal meningitis or extragenital gonococcal infection. Patients with **C9 deficiency** retain about half-normal CH_{50} titers; a third of these patients have had *Neisseria* disease. In studies of patients 10 years or older with systemic meningococcal disease, 3–15% have had a genetic deficiency of C5, C6, C7, C8, C9, or properdin. When the infection was caused by an uncommon serogroup (X, Y, Z, W135, 29E, or nongroupable; not A, B, or C), 33–45% of patients had an underlying complement deficiency. It is not clear why patients with a deficiency of one of the late-acting components suffer a particular predisposition to

Neisseria infections; it may be that serum bacteriolysis is uniquely important in defense against this organism. Some persons with such a deficiency have had no significant illness.

A few individuals have had **factor D deficiency** of the alternative pathway. All have had recurrent infections, often due to *Neisseria*. Hemolytic complement activity in their serum was normal, but alternative pathway activity was markedly deficient or absent.

MBL is an important component of the innate immune system, which protects against infection as the specific immune response emerges. Polymorphisms in the promoter region of the gene encoding MBL and mutations in the structural gene result in pronounced inter-individual variation in the level of circulating MBL. A very low level **(MBL deficiency)** predisposes to recurrent pyogenic and fungal infections, most commonly in

infants and young children, but 90% of MBL deficient individuals do not have recurrent infections.

Almost all of the complement components are inherited as autosomal recessive traits of the autosomal co-dominant variety; that is, each parent transmits a gene that codes for synthesis of half the serum level of the component. Deficiency results from inheritance of one null gene from each parent; the hemizygous parents typically have CH_{50} levels that are low normal. Inheritance of deficiency of factors D and B is uncertain but probably also autosomal recessive. Properdin deficiency is transmitted as an X-linked trait.

124.3 Deficiencies of Plasma, Membrane, or Serosal Complement Control Proteins

Congenital deficiencies of 5 plasma complement control proteins have been described (see Table 124–1). **Factor I deficiency** was originally reported as a deficiency of C3 as a result of its hypercatabolism. The first patient described had suffered a series of severe pyogenic infections similar to those seen with agammaglobulinemia or congenital deficiency of C3. Further studies indicated that the primary deficiency was that of factor I, an essential regulator of both pathways. This deficiency permits prolonged existence of C3b in the C3 convertase of the alternative pathway, C3bBb, resulting in constant activation of the alternative pathway and cleavage of more C3 to C3b, in circular fashion. Intravenous infusion of plasma or purified factor I induced a prompt rise in serum C3 concentration in the patient and a return to normal of in vitro C3-dependent functions such as opsonization.

The effects of **factor H deficiency** are like those of factor I deficiency because factor H assists in dismantling the alternative pathway C3 convertase. Levels of C3, factor B, total hemolytic activity, and alternative pathway activity have been low or undetectable in all patients tested. Patients have sustained systemic infections due to pyogenic bacteria, particularly meningococci, and almost half of the cases have had glomerulonephritis. The few patients thus far reported as having **C4-binding protein deficiency** have had about 25% of the normal levels of the protein and no typical disease presentation, although one had angioedema and Behçet's disease.

Persons with **properdin deficiency** have had a striking predisposition to meningococcal meningitis. All reported patients have been male. The predisposition to infection in these patients demonstrates clearly the need for the alternative pathway in host defense against bacterial infection. Serum hemolytic complement activity is normal in these patients, and if the patient has specific antibacterial antibody, the need for the alternative pathway and properdin is greatly reduced. Several patients have had dermal vasculitis or discoid lupus.

Hereditary angioedema occurs in persons born without the ability to synthesize normally functioning C1 inhibitor (C1 INH). In 85% of affected families, the patient has markedly reduced concentrations of inhibitor (5–30% of normal); in the other 15%, normal or elevated concentrations of an immunologically cross-reacting but nonfunctional protein occur. Both forms of the disease are transmitted as an autosomal dominant trait.

In the absence of C1 INH functions, activation of C1 leads to uncontrolled C1 activity, with breakdown of C4 and C2 and release of vasoactive peptides (kinins), which results in episodic, localized, nonpitting edema from the vasodilatory effects of the kinins on the postcapillary venule. The mechanism by which C1 is activated in these patients is not clear.

Swelling of the affected part progresses rapidly, without urticaria, itching, discoloration, or redness, and often without severe pain. Swelling of the intestinal wall, however, can lead to intense abdominal cramping, sometimes with vomiting or diarrhea; concomitant subcutaneous edema is often absent, and patients have undergone abdominal surgery or psychiatric examination before the true diagnosis was established. Laryngeal edema can be fatal. Attacks last 2–3 days and then gradually abate. They may occur at sites of trauma, after vigorous exercise, with menses, or with emotional stress. Attacks can begin in the first 2 years of life but are usually not severe until late childhood or adolescence. **Acquired C1 INH deficiency** can occur in association with B-cell cancer or autoantibody to C1 INH. SLE and glomerulonephritis have been reported in patients with the congenital disease.

Three of the membrane complement control proteins, CR1, membrane cofactor protein, and decay-accelerating factor (DAF), prevent the formation of the full C3-cleaving enzyme, C3bBb, which is triggered by C3b deposition. CD59 (membrane inhibitor of reactive lysis) prevents the full development of the membrane attack complex that creates the “hole.” **Paroxysmal nocturnal hemoglobinuria (PNH)** is a hemolytic anemia that occurs when DAF and CD59 are not expressed on the erythrocyte surface. The condition is acquired as a somatic mutation in a hematopoietic stem cell of the *PIG-A* gene on the X chromosome. The product of this gene is required for normal synthesis of a glycosyl-phosphatidylinositol molecule that anchors about 20 proteins to cell membranes, including DAF and CD59. One patient with **genetic isolated CD59 deficiency** had a mild PNH-like disease in spite of normal expression of membrane DAF. In contrast, **genetic isolated DAF**

deficiency has not resulted in hemolytic anemia.

Patients with SLE and their asymptomatic family members have a partial **CR1 deficiency**, which is possibly inherited. This deficiency could increase the risk of developing immune complex disease, thereby contributing to the pathogenesis of SLE.

Serosal fluids contain a protease that normally destroys the chemotactic activity of C5a and interleukin 8 (IL-8), important chemotactic factors for neutrophils. A defect in this protease in peritoneal and synovial fluids occurs in **familial Mediterranean fever**. Patients have a missense mutation in a gene encoding a transcription factor termed **pyrin**, which may represent the basic defect. They suffer recurrent episodes of fever in association with painful inflammation of joints and pleural and peritoneal cavities (Chapter 153). Thus, it appears that C5a or IL-8 or both are generated at serosal surfaces under normal conditions and that serosal fluids contain an inhibitor of these chemotactic agents that serves to prevent the inflammatory response that would otherwise ensue.

124.4 Secondary Disorders of Complement

Partial deficiency of C1q has occurred in patients with severe combined immunodeficiency disease or hypogammaglobulinemia, apparently secondary to the deficiency of IgG, which normally binds reversibly to C1q and prevents its rapid catabolism.

Plasma from patients with chronic membranoproliferative glomerulonephritis (MPGN) contains a protein termed **nephritic factor** (NeF) that promotes activation of the alternative pathway. NeF is an IgG antibody to the C3-cleaving enzyme of the alternative pathway, C3bBb, which protects the enzyme from inactivation. The result is increased consumption of C3. Serum C3 concentrations vary widely from patient to patient, however. Pyogenic infections, including meningitis, may occur if the serum C3 level drops below about 10% of normal. This disorder has been found in children and adults with *partial lipodystrophy.* Adipocytes are the main source of factor D and synthesize C3 and factor B; exposure to NeF induces their lysis. An IgG nephritic factor that binds to and protects C42, the classical pathway C3 convertase, has been described in acute postinfectious

nephritis and in SLE. The consumption of C3 that characterizes poststreptococcal nephritis and SLE could be due to this factor, to complement activation by immune complexes, or to both. A patient has been described with a circulating inhibitor of factor H and hypocomplementemic MPGN, emphasizing the importance of factor H in restraining the uncontrolled conversion of C3.

Newborn infants have mild to moderate deficiencies of all plasma components of the complement system. Opsonization and generation of chemotactic activity in serum from full-term newborns can be markedly deficient through either the classical or the alternative pathway. Complement activity is even lower in preterm infants. Patients with severe chronic cirrhosis of the liver, hepatic failure, malnutrition, or anorexia nervosa may also have significant depletion of components and functional activity of complement. Although synthesis of components is depressed in these conditions, serum from some patients with malnutrition also appears to contain immune complexes that could accelerate depletion.

Patients with sickle cell disease have normal activity of the classical pathway, but some have defective function of the alternative pathway in opsonization of *Streptococcus pneumoniae*, in bacteriolysis and opsonization of *Salmonella*, and in lysis of rabbit erythrocytes. Deoxygenation of erythrocytes from patients with sickle cell disease alters their membranes to increase exposure of phospholipids that can activate the alternative pathway and consume its components. This activation is accentuated during painful crisis. An alternative pathway defect has been described in about 10% of individuals who have undergone splenectomy and in some patients with ß-thalassemia major. The underlying mechanism for this defect in these last two conditions is not known. Children with nephrotic syndrome may have subnormal serum opsonizing activity in association with decreased serum levels of factors B and D.

Immune complexes initiated by microorganisms or their by-products can induce complement consumption. Activation occurs primarily through fixation of C1 and initiation of the classical pathway. In SLE, immune complexes activate C142, and C3 is deposited at sites of tissue damage, including kidneys and skin; depressed synthesis of C3 is also noted. Formation of immune complexes and consumption of complement have been demonstrated in lepromatous leprosy, bacterial endocarditis, infected ventriculojugular shunts, malaria, infectious mononucleosis, dengue hemorrhagic fever, and acute hepatitis B. Nephritis or arthritis may develop as a result of deposition of immune complexes and activation of complement in these infections. The syndrome of recurrent urticaria, angioedema, eosinophilia, and hypocomplementemia secondary to activation of the classical pathway may be due to circulating immune complexes. Circulating immune complexes and decreased C3 have been reported in some patients with dermatitis herpetiformis, celiac disease, primary biliary cirrhosis, and Reye syndrome.

In patients with bacteremic shock, bacterial products appear to initiate direct activation of the alternative pathway. Intravenous injection of iodinated roentgenographic contrast medium can trigger a rapid and significant activation of the alternative pathway, which may explain at least some of the occasional reactions that occur in patients undergoing this procedure.

Burns can induce massive activation of the complement system, especially the alternative pathway, within a few hours after injury. Generation of C3a and C5a occurs, which stimulates neutrophils and induces their sequestration in the lungs. These events may play an important part in the development of shock lung after burn injury. Cardiopulmonary bypass, plasma exchange, or hemodialysis using cellophane membranes may be associated with a similar syndrome due to activation of plasma complement, with release of C3a and C5a. In patients with erythropoietic protoporphyria or porphyria cutanea tarda, exposure of the skin to light of certain wavelengths activates complement, generating chemotactic activity. Phototoxicity is associated histologically with lysis of capillary endothelial cells, mast cell degranulation, and the appearance of neutrophils in the dermis.

124.5 Treatment of Complement Disorders

No specific therapy is available at present for genetic deficiencies of the complement system except hereditary angioedema, but a great deal can be done to protect patients with any of these disorders from serious complications. Management of hereditary angioedema starts with avoidance of precipitating factors, usually trauma. Infusion of vapor-heated C1 INH concentrate, not yet available in the U.S., aborts acute attacks and is safe and effective in long-term prophylaxis or in preparation for surgery or dental procedures. Adults with hereditary angioedema respond to danazol, a synthetic androgen with weak virilizing and mild anabolic potential. The drug, given orally, increases the level of C1 INH several-fold and prevents attacks. It has not been recommended for use in children.

Effective supportive management is available for other primary diseases of the complement system. Identification of a specific defect in the complement system may have an important impact on management. Concern for the associated complications, such as autoimmune disease and infection, should encourage vigorous diagnostic efforts and earlier institution of therapy. Individuals with SLE and a complement defect generally respond as well to therapy as those without complement deficiency. With the onset of unexplained fever, cultures should be obtained and antibiotic therapy instituted more quickly and with less stringent indications than in a normal child. The parent or patient should be given letters describing any predisposition to systemic bacterial infection associated with the patient's deficiency, along with the recommended approach to management, for possible use by school, camp, or emergency room physicians. The patient and close household contacts should be immunized with vaccines for *Haemophilus influenzae, S. pneumoniae*, and *N. meningitidis.* High titers of specific antibody might opsonize effectively without the full complement system, and immunization of household members could reduce the risk of exposing patients to these particularly threatening pathogens.

Chapter 125 - Clinical Indications

ACQUIRED DISEASES

Aplastic Anemia.

Aplastic anemia, a disorder of unknown cause, results in pancytopenia and bone marrow hypoplasia and, if severe (platelet <20,000/mm^3 ; absolute neutrophil count <500/mm^3 ; or reticulocyte count <1% when anemia is present), often results in death within the first 6 mo from infection or bleeding. The marrow dysfunction may result from inherited disorders (e.g., Fanconi anemia or paroxysmal nocturnal hemoglobinuria), autoimmunity, or dysregulated cytokine production, and is occasionally associated with exposure to chemicals (e.g., benzene or chloramphenicol) and non-A, non-B, non-C hepatitis. Blood transfusion should be avoided if possible, because sensitization to blood products increases the likelihood of graft rejection should SCT be needed. SCT is the treatment of choice for patients with severe aplastic anemia who have an HLA-matched family donor; the 2-yr survival rate is 69%, based on data from the International Bone Marrow Transplant Registry. The 15-yr survival rate was 100% among children younger than 6 yr of age (n = 12) and 78% for children 6–19 yr of age (n = 63) receiving HLA-matched sibling SCT in Seattle for aplastic anemia.

Patients transplanted for aplastic anemia exhibit a higher incidence of graft rejection than seen with other kinds of HLA-matched sibling transplants, but the addition of antithymocyte globulin (ATG) to cyclophosphamide for the preparative regimen decreases rejection significantly. Since the institution of this preparative regimen, an actuarial 3-yr survival rate of 92% has been achieved (Fig. 125–1). Transplantation using unrelated donors requires further immunosuppressive therapy, including the addition of irradiation and/or chemotherapy, resulting in a 5-yr survival of 69%. The added therapy has the drawback of an increased incidence of secondary cancers, especially in patients with underlying Fanconi anemia.

Acute Myelogenous Leukemia.

Acute myelogenous leukemia (AML) is a heterogeneous group of leukemias derived from myeloid progenitor cells (see Chapter 487–2). SCT is the accepted therapy for AML in first remission. Disease-free survival (DFS) rates range from 55–83% for matched sibling SCT performed during the first complete remission. In a randomized trial in 271 children with AML in first remission following intensive-timed induction therapy, 8-yr DFS rates were 70% for matched sibling SCT, 54% for high-dose chemotherapy alone, and 57% for autologous SCT.

Figure 125-1 Marrow grafts for aplastic anemia (AA). Kaplan-Meier estimates of survival in 78 patients with aplastic anemia given HLA-identical marrow transplants. Thirty-nine were conditioned with cyclophosphamide/antithymocyte globulin (current patients), and 39 received cyclophosphamide alone (historical patients). Tick marks indicate surviving patients. (From Storb R, Leisenring W, Anasetti C, et al: Long-term follow-up of allogeneic marrow transplants in patients with aplastic anemia conditioned by cyclophosphamide combined with antithymocyte globulin. *Blood* 1997;89:3890–91.)

SCT also improves survival of children with acute megakaryocytic (M7) leukemia and secondary AML resulting from prior cancer therapy, both of which respond poorly to chemotherapy. SCT is indicated for patients with AML who do not achieve remission, using stem cells from an HLA-identical family donor, mismatched family donor, or unrelated donor. In patients with AML who achieve a first remission, SCT is indicated if they have an HLA-identical family donor. One exception to this strategy is M3 or promyelocytic leukemia, which is quite responsive to all-*trans*-retinoic acid and consolidation chemotherapy. Patients with AML who relapse or are in second remission should be considered for SCT using an HLA-matched family donor, unrelated donor, or previously stored autologous marrow. Patients with numerous relapses, resistant disease, or secondary AML are candidates for higher-risk mismatched SCT.

Acute Lymphoblastic Leukemia.

Acute lymphoblastic leukemia (ALL) is the most common malignancy of childhood, and 70–80% of cases are cured by conventional chemotherapy (see Chapter 487–1). A subgroup of these patients are at high risk for relapse with conventional therapy (75–100%) and should be

considered for SCT (Box 125–1). DFS rates range from 15–65%, with relapse rates of 30–70%.

Patients with high-risk ALL who have HLA-matched donors may be eligible for allogeneic SCT. Children receiving HLA-matched sibling SCT for high-risk ALL in first complete remission have DFS rates of 70–80% with low relapse rates of 0–10%, although the numbers are small and some high-risk groups such as Philadelphia

chromosome–positive ALL have lower survival rates at 50–65%. Patients who do not have high-risk features at the time of diagnosis but who later suffer relapse and have an HLA-identical family donor also benefit from SCT, with DFS rates of 40–60%. Patients have a better outcome if they undergo transplantation in remission, and patients in whom remission occurs earlier have a higher DFS rate. Patients without a family donor may benefit from unrelated donor or cord blood transplant, with DFS rates of 30–40%.

Comparisons of allogeneic and autologous SCT or chemotherapy for ALL relapse support the recommendation that these children should be offered SCT when possible. A review of 376 children receiving HLA-identical sibling SCT compared with 540 children receiving chemotherapy for ALL in second remission revealed DFS rates of 40% and 17%, with relapse rates of 45% and 80%, respectively. Other studies comparing allogeneic and autologous SCT for relapsed ALL have shown DFS rates of 33–61% for allografts and 21–47% for autografts, illustrating the advantage of allogeneic SCT over autologous transplants despite increased toxicity.

The lower incidence of relapse in allogeneic SCT is related to a graft versus host disease (GVHD)/graft versus leukemia (GVL) effect. The probability of relapse was 25 ± 6%, 22 ± 5%, 10 ± 7%, 7 ± 3%, 46 ± 15%, and 41 ± 8% for allogeneic grafts without GVHD, acute GVHD only, chronic GVHD only, acute and chronic GVHD, syngeneic grafts, and allogeneic T cell–depleted grafts, respectively. These results are the same for lymphoblastic and myelogenous leukemia, emphasizing the importance of the immune system in eliminating residual leukemia cells. This concept has been taken a step further with the recent use of low-intensity nonmyeloablative transplant regimens that rely on GVL as a primary therapeutic modality.

Infant leukemia (see Chapter 487.6) occurring within the first 12 mo of life is rare and carries a very poor prognosis, with survival rates of 20–30% after 5 yr with conventional chemotherapy. Cytogenetic abnormalities such as t(4;11)(q21;q23) involving the *MLL* gene (60–70% of cases) and poor response to corticosteroids are recognized as poor prognostic indicators. Infants with a normal 11q23 locus have a very good response to conventional chemotherapy, with a DFS of 80% at a median follow-up of 46 mo, whereas those with a rearranged 11q23 have a very poor response, with a 15% DFS. Studies suggest that SCT is beneficial in these high-risk infants, with DFS rates of 40–50% for patients transplanted in remission compared with 10–20% if SCT is performed after relapse, using various sources of marrow. Children diagnosed within the 1st year of life with acute leukemia with chromosomal rearrangements involving 11q23

Box 125-1. Risk Factors for Relapse of Acute Lymphoblastic Leukemia (ALL) with Conventional Chemotherapy Alone

Congenital or infant (<1 yr of age) ALL

Chromosomal translocations: t(4,11), t(9,22)-Philadelphia, t(8,14)

FAB L3 morphology (Burkitt)

White blood cell count =100,000/mm^3

More than 1 mo to achieve initial remission

Failure to achieve a remission

Relapse while on chemotherapy

Second and subsequent remissions (when first remission < 30 mo)

More than one extramedullary site of relapse without a marrow relapse

Secondary ALL resulting from prior cancer therapy

are best treated with intense induction chemotherapy followed by bone marrow transplantation if a suitable donor is available.

Myelodysplastic and Myeloproliferative Disorders.

Myelodysplastic syndrome (MDS) includes a group of disorders with defects in hematopoietic cell development close to the level of the marrow stem cell, which eventually progresses from a picture of dysplastic ineffective hematopoiesis to aggressive overt myelogenous leukemia. These are classified as refractory anemia, refractory anemia with ringed sideroblasts, refractory anemia with excess blasts, refractory anemia with excess blasts in transformation, and chronic myelomonocytic leukemia (CML). Because of the close relationship to AML, patients with MDS are treated according to AML protocols. The transplant outcome in patients with MDS is similar to that in patients with AML. In one series of 23 pediatric patients, the DFS at 5 yr was 64% using HLA-matched family donors, and for 15 pediatric patients receiving HLA-matched unrelated donor SCT the DFS was 53%. Transplant should be considered early after diagnosis because patients in whom the disease has

progressed with increasing blasts have a much poorer outcome and a higher rate of relapse. Conventional chemotherapy and other nontransplant forms of treatment have not made a significant impact of the natural progression of the disease.

These disorders are characterized by a single lineage myeloid proliferation that can progress to an AML-like leukemia and include CML, essential thrombocythemia (ET), polycythemia vera (PV), agnogenic myeloid metaplasia, and juvenile chronic myelogenous leukemia (JCML), also known as juvenile myelomonocytic leukemia. SCT is the treatment of choice for CML (see Chapter 487.5). HLA-identical sibling transplantation results in an 80% long-term DFS compared with 45–74% for matched unrelated SCT. Transplantation is recommended within 1 yr from diagnosis, because delay results in a significant decrease in the DFS to 40–60%. Patients receiving SCT in accelerated phase or blast crisis have DFS rates of 35–40% and 10–20%, respectively, and a 60% chance of relapse compared with a 10–20% chance of relapse in patients receiving SCT in chronic phase.

Successful SCT has also been performed for some of the more uncommon myeloproliferative disorders. SCT should be considered in those patients who fail to respond to conservative management or whose disease progress to an AML-like leukemic condition. SCT is a possible approach for childhood polycythemia vera. SCT has been attempted for ET in a few patients without success. AMM, or idiopathic myelofibrosis, is characterized by splenomegaly and progressive fibrosis of the marrow compartment, resulting in anemia. The mean survival for patients with AMM is 5 yr, and the only known curative therapy is SCT; 7 of 12 patients receiving SCT for AMM survived.

JCML is an aggressive clonal proliferation of immature myeloid precursors associated with neurofibromatosis type 1 and monosomy 7. The clinical course is rapid, with resistance to conventional chemotherapy and death at an average of 9 mo from the time of diagnosis. SCT is curative in these patients and should be pursued aggressively once the diagnosis is confirmed. Multiple studies have yielded DFS rates of 30–40% after receiving SCT from matched sibling donors and 20–30% from mismatched family members/matched unrelated donors. The association of JCML with NF-1 resulting in dysregulation of the *RAS* oncogene and the known response of JCML to retinoic acid has led to current therapy using farnesyl transferase inhibitors, chemotherapy, retinoic acid, and SCT.

Lymphomas.

Non-Hodgkin lymphoma (NHL) and Hodgkin disease (HD) are malignant, usually clonal proliferations arising from the lymphoreticular system (see Chapter 488). Childhood lymphomas are quite responsive to conventional chemoradiotherapy, but a subset of these patients have high-risk disease and relapse, requiring more intensive therapy to achieve a cure. SCT

can cure some patients with NHL and HD and should be offered early after relapse, while the disease is still sensitive to therapy, there is little bulky disease, and there is a greater likelihood of being able to tolerate a transplant regimen. Patients with sensitive disease and little tumor burden have favorable outcomes, with DFS rates of 50–60%, whereas high-risk patients with bulky tumor or refractory disease have a poor outcome with survival rates of 10–20%. Pretransplant salvage chemotherapy including the use of antibodies targeted to specific tumor antigens such as CD20 may be of some benefit to reduce the tumor burden. If an HLA-identical sibling is available, allogeneic transplant should be offered to take advantage of the GVL effect, which has reduced the relapse rate by as much as 25–30% in some series. Use of autologous peripheral blood stem cell transplant (PBSCT) has resulted in earlier engraftment and a decrease in transplant-related morbidity, although the potential for contamination with tumor cells remains. A European Lymphoma Registry study described autologous SCT for children with poor-risk B-cell or Burkitt lymphoma, including those with relapsed or resistant disease. The 5-yr DFS rate was 39.4% in these children with otherwise incurable disease. In a report from six Spanish centers, 46 pediatric patients received SCT for NHL, including lymphoblastic lymphoma, Burkitt, and large cell lymphoma, with a 3-yr DFS rate of 58%. A separate but distinct clinicopathologic entity is the CD30 or Ki-1 positive peripheral T-cell lymphomas including anaplastic large cell lymphomas associated with chromosomal translocation t(2;5). These tumors are aggressive and tend to relapse but have responded well to SCT, with an 80% 5-yr DFS rate.

Hematopoietic SCT has resulted in improved survival for patients with relapsed or refractory Hodgkin's disease, with most series reporting 40–60% DFS rates after 2–5 yr. Using the risk factors of more than one extranodal site of disease, performance status, and progressive disease at the time of transplant, low-risk patients (no risk factors) have a 3-yr DFS rate of 82%, whereas intermediate-risk (one risk factor) and high-risk (two to three risk factors) patients had DFS rates of 56% and 19%, respectively.

Finally, there are several reports of successful SCT performed in children with Langerhans cell histiocytosis, including histiocytosis X (see Chapter 499). Although patients with single-organ involvement histiocytosis fare quite well, patients with multiorgan involvement respond poorly to conventional therapy and should be considered for SCT.

Neuroblastoma.

The most common extracranial solid tumor in children is neuroblastoma (see Chapter 490). Although SCT studies show a trend for improvement over those obtained with chemotherapy, randomized trials to compare the two approaches are ongoing. DFS (3 yr) rates for patients receiving SCT after progression of disease are 7–25%, compared with 25–55% for those receiving SCT before progression of disease. Certain high-risk groups have a significant improvement with SCT, including those with *NMYC* amplification, 2 yr of age and older, a partial remission to induction therapy, and bone/bone marrow metastasis. In a Children's Cancer Group study, high-risk patients received chemotherapy, radiation, and surgery and then were randomized to receive autologous SCT and 13-*cis*-retinoic acid (RA), resulting in 3-yr DFS rates for chemotherapy, chemotherapy plus RA, SCT, and SCT plus RA of 18%, 32%, 40%, and 55%, respectively, reflecting the role of biologic agents such as RA as adjuncts to cytotoxic therapy by inducing ganglioneuronal differentiation in neuroblastoma.

Brain Tumors.

Tumors of the central nervous system (CNS) are the most common solid tumors in children, accounting for 20% of childhood malignancies (see Chapter 489). For children with disease resistant to conventional chemotherapy and irradiation, the dose-limiting toxicity for intensifying therapy is myelosuppression, thus providing a role for stem cell rescue. Early results from a multi-institutional study are encouraging in a group of 53 patients with high-risk (19) or average-risk (34) medulloblastoma or supratentorial primitive neuroectodermal tumors (PNET) that were treated sequentially with surgery-topotecan-irradiation followed by four cycles of cyclophosphamide, cisplatin, and vincristine with PBSC support. The 2-yr progression-free survival rates were 93% and 73% in average-risk and high-risk patients, respectively. The Italian group treated 11 children with recurrent medulloblastoma (3), glioblastoma multiforme (2), PNET (2), ependymoma (2), anaplastic astrocytoma (1), and anaplastic oligodendroglioma (1) using a conditioning regimen of etoposide and *bis*-chlorethylnitrosourea (BCNU) or thiotepa followed by autologous marrow infusion; 5 children who had no measurable disease at the time of transplant are alive without evidence of disease after follow-up for a median of 20 mo. A Children's Cancer Group study used carboplatin, thiotepa, and etoposide as a preparative regimen for 23 patients with recurrent medulloblastoma, resulting in a 34% DFS rate after 3 yr. Another study focused on using a similar chemotherapy-only transplant regimen following standard induction therapy (vincristine, cisplatin, cyclophosphamide, and etoposide) for young children with newly diagnosed brain tumors (malignant glioma, 9; ependymoma, 10; brainstem glioma, 6; medulloblastoma, 13; PNET, 14; other, 10) in an effort to avoid the toxicity of cranial radiation; of 62 children enrolled, 37 had no disease progression with induction therapy and went on to autologous marrow transplant with a DFS rate of 41% (27% for all 62 enrolled) after 2 yr.

Solid Tumors.

Many solid tumors are quite responsive to conventional chemoradiotherapy; however, a subset of these are associated with a very poor prognosis. These tumors are high risk by virtue of their histology (alveolar rhabdomyosarcomas, anaplastic Wilms tumor), location (pelvic, trunk, or proximal extremity Ewing sarcoma, axial skeletal osteogenic sarcoma), or widespread metastatic presentation. Stem cell rescue allows dose intensification of chemotherapy with or without total body irradiation (TBI). The French Society of Pediatric Oncology reported 28 children who received autologous SCT for refractory or relapsed Wilms tumor (see Chapter 491) using melphalan, etoposide, and carboplatin as a conditioning regimen. Twelve of 28 children remain disease free a median of 48 mo after SCT with a 3-yr DFS rate of 50%. In an update by the European Intergroup Study of high advanced Ewing sarcomas using TBI, melphalan, etoposide, and carboplatin, 9 of 36 patients receiving either autologous or allogeneic SCT survive after 5 yr, with a somewhat poorer DFS for the allogeneic group (20% vs. 25%), owing to toxicity. A more encouraging response was obtained, although with a shorter follow-up, with the use of tandem autologous PBSCT for Ewing sarcoma. After receiving etoposide, carboplatin, and cyclophosphamide followed by stem cell rescue, a second cycle using melphalan and TBI was given 4–6 weeks later with a 3-yr DFS rate of 56%. SCT for high-risk or relapsed rhabdomyosarcoma has been disappointing. In a retrospective review by German/Austrian Transplant Group from multiple centers with eight different conditioning regimens, 9 of 36 patients survive with a median follow-up of 57 mo, showing little difference from salvage chemotherapy regimens. There have been several reports of autologous SCT for retinoblastoma with a 3-yr DFS rate of 67%, with those patients with distant metastasis doing the best and those with CNS extension having a poorer outcome. The most exciting result in SCT for solid tumors comes from studies using less intensive nonmyeloablative PBSCT for refractory renal cell carcinoma. Low-dose therapy (cyclophosphamide and fludarabine) allows engraftment of allogeneic donor T cells to generate a graft versus tumor effect. Nine of 19 patients survive with a median follow-up of 402 days, with 3 patients without evidence of disease. Similar studies are being pursued for other solid tumors.

GENETIC DISEASES

Immunodeficiency Disorders.

SCT is the treatment of choice for severe combined immunodeficiency (SCID; see Chapter 116.1). The DFS rate using matched sibling donors is more than 90%, and using T-depleted mismatched family member grafts it is 60–80%. There is less experience with unrelated donor SCT for SCID, but nonetheless it has also been effective. SCT has been performed in other forms of immune deficiency, including Wiskott-Aldrich syndrome, DiGeorge syndrome, Kostmann neutropenia, leukocyte adherence deficiency, chronic granulomatous disease, Chédiak-Higashi syndrome, familial erythrophagocytic lymphohistiocytosis, Duncan syndrome, and neutrophil actin deficiencies. Survival rates are 68% when matched sibling donors are used and 35% when mismatched donors are used. The presentation of DiGeorge syndrome can be variable; however, those patients with initial profoundly depressed T-cell function do not recover over time and are candidates for SCT. If other forms of therapy are available, such as interferon-? for chronic granulomatous disease or granulocyte colony-stimulating factor (G-CSF) for Kostmann neutropenia, SCT should be reserved for patients who are unresponsive. Other approaches that are promising in these disorders are less toxic nonmyeloablative SCT and gene therapy targeting the specific gene deficiency.

Fanconi Anemia (see Chapter 460).

The characteristic sensitivity to DNA cross-linking agents makes children who have Fanconi anemia (FA) quite sensitive to conventional SCT conditioning regimens, requiring dose reduction to avoid excessive toxicity. Transplant-related toxicities include severe oral mucositis, hemorrhagic cystitis, erythroderma, and GVHD. DFS rates are 25–75%, depending on the source of stem cells. Patients receiving reduced conditioning regimens and matched sibling donor SCT have the best outcomes, although mismatched and unrelated donor SCT have been successful. Patients with FA and an HLA-identical family member who has a negative FA screen should be offered SCT at the first sign of pancytopenia. Alternative donor transplants including cord blood should be considered in the absence of a matched family member, given the poor outlook for these patients once leukemic transformation

occurs.

Storage Diseases.

The metabolic storage diseases are a heterogeneous group of disorders resulting from single gene mutations producing enzyme defects and the subsequent toxic accumulation of metabolites. The end result is progressive neurologic deterioration or visceral infiltration, which is usually fatal. Some disorders, such as adrenoleukodystrophy, respond to dietary measures, whereas others, such as Gaucher disease types I and III, respond to enzyme supplementation; however, in most cases there is no successful supplementation therapy available. SCT provides a source of enzyme through the bone marrow–derived monocyte/phagocytic cell system, which includes the liver (Kupffer cells), brain (microglia), skin (Langerhans cells), marrow (osteoclasts), lung (pulmonary macrophage), and lymph nodes (histiocytes). The results of transplant in several storage disorders are variable, with some patients showing a good response (adrenoleukodystrophy, metachromatic leukodystrophy, globoid cell leukodystrophy, Hurler syndrome), whereas other results have been more dismal (Sanfilippo and Hunter syndromes). The risk of transplant-related mortality is about 10% for matched sibling donors and 37% in mismatched and unrelated donors. Transplant before the disease progresses to extensive end-organ damage is necessary. Efforts should be directed toward early diagnosis and SCT before significant neurologic damage occurs.

Thalassemia

(see Chapter 454.9). Three risk factors that influence the outcome of SCT for thalassemia include hepatomegaly, portal fibrosis, and a history of inconsistent iron chelation before transplant. Other factors, such as the number of transfusions, ferritin level, degree of hemosiderosis, hepatic iron concentration, and splenomegaly, have no effect. Patients are classified as class 1, no risk factors; class 2, one to two risk factors; and class 3, all three risk factors. In Italy, more than 500 children age 16 yr or older have received HLA-identical family member SCT (Fig. 125–2). DFS rates of up to 90% are obtained in children undergoing transplants before the development of hepatomegaly or portal fibrosis. Hepatic hemosiderosis and portal fibrosis may improve after transplant if the damage is not too extensive. In the United States, 17/27 children (63%) who received HLA-matched family donor SCT survived disease free; 1 required a second SCT. Another 5 patients survived after graft rejections and lived with recurrent thalassemia for an overall survival of 81%. If an HLA-identical family member is available, SCT should be performed before the patient develops advanced disease. Unrelated donor SCT also have been performed with carefully matched donors, but at a cost of somewhat higher toxicity but a similar DFS.

Sickle Cell Disease

(see Chapter 454.1). With supportive care, more than 90% of children with sickle cell disease live into their 3rd and 4th decades, and 60% survive to age 50 yr. Disease severity varies among patients with homozygous hemoglobin S (HbS) disease; 5–20% suffer significant morbidity from vaso-occlusive crises and pulmonary, renal, and CNS damage. New approaches include antisickling agents, gene therapy, and induction of increased hemoglobin F by drugs such as hydroxyurea, but SCT is the only curative treatment for sickle cell disease.

In the United States, 50 patients (ages 3–15 yr) with sickle cell disease have received SCT using HLA-identical sibling donors; two donors had sickle trait. The indications for SCT included history of strokes, recurrent acute chest syndrome, or recurrent vaso-occlusive crises. Forty-seven survive (94%), with 5 patients (10%) experiencing graft rejection or recurrence of sickle cell disease, for a DFS rate of 84% at a median follow-up of 38 mo. Forty-five patients (ages 1–23 yr) received HLA-identical family member SCT for SS disease in Belgium and France. After follow-up of 1–75 mo, 95% survive with a DFS rate of 86%. No vaso-occlusive events have occurred among the 38 patients with successful engraftment, and some have recovered splenic function. Although SCT can cure homozygous HbS disease, selecting appropriate candidates for SCT is difficult.

Figure 125-2 The probabilities of rejection-free survival for 271 patients younger than 17 yr of age with thalassemia who received marrow transplants from HLA-identical family members after conditioning with busulfan and cyclophosphamide. (From Forman SJ, Blume KG, Thomas ED: *Bone Marrow Transplantation.* Boston, Blackwell, 1994.)

Patients with SS disease may survive for decades, but some patients have a poor quality of life, with repeated hospitalizations for painful vaso-occlusive crises and CNS infarcts. SS patients, such as those with the Central African Republic haplotype, can be predicted to have serious complications. SCT should be considered in young patients who have recurrent severe vaso-occlusive crises, evidence of developing end-organ damage, CNS infarcts, or a history of strokes and have an HLA-identical family member donor.

Other Congenital Anemias.

SCT is successful in some other congenital anemias. Diamond-Blackfan syndrome or congenital pure red cell aplasia is characterized by normochromic-macrocytic anemia with a normocellular marrow (see Chapter 440). Patients who fail to respond to initial therapies may benefit from SCT using an HLA-identical sibling donor. Thirty-one of 40 patients who were given SCT for Diamond-Blackfan anemia are alive with a 2-yr DFS rate of 72%. Congenital sideroblastic anemia results from a mitochondrial abnormality in erythroblasts (see Chapter 448). One 34-mo-old child received an SCT from a phenotypically identical cousin and has some persistent liver enlargement after 3 yr but remains transfusion independent with normal serum iron and ferritin levels. There are also reports of curative allogeneic SCT for Shwachman-Diamond syndrome, an autosomal recessive disorder characterized by exocrine pancreatic dysfunction, metaphyseal dysostosis, and marrow dysfunction, including leukemic transformation.

Chapter 126 - Matching and Rejection

The long-standing immunologic goal of stem cell transplantation (SCT) has been a graft that can respond to foreign antigens without reacting to the host and that is not rejected; however, current approaches to SCT are now using the immunologic differences between the donor and host tumor antigens as a primary therapeutic modality in nonmyeloablative SCT. These transplants use smaller doses of total body irradiation (TBI) or chemotherapy that supply enough immunosuppression to allow allogeneic donor stem cells to engraft and “reject” the patient's tumor. This technique is also useful in providing a source of donor cells to correct nonmalignant disorders (inborn errors of metabolism, immunodeficiencies, autoimmune disorders, hemoglobinopathies, osteopetrosis) and avoiding the toxic higher doses of TBI and chemotherapy. The tradeoff of this approach is graft versus host disease (GVHD) and risk of rejection.

The most important factor determining tolerance is the histocompatibility between the donor and host. The genes defining histocompatibility are encoded in the **major histocompatibility complex (MHC),** which spans approximately 4,000?kb on the short arm of chromosome 6 and contains the genes for a series of cell surface glycoproteins termed the **human leukocyte antigens (HLA).** The HLA genes are tightly linked and can be divided into class I glycoproteins that dimerize with $ß_2$ -microglobulin and class II glycoproteins with a and ß peptides that form heterodimers. Although there are more than 35 HLA class I and II genes and more than 1,336 alleles, HLA-A and HLA-B (class I) and HLA-DRB1 (class II) genes are used as the primary determinants for histocompatibility of donors and recipients for SCT. The HLA genes on a single chromosome 6 make up a **haplotype** that, along with the HLA genes on the other copy of chromosome 6, constitute the **genotype.** Class I genes are determined by serotyping, isoelectric focusing gel electrophoresis, and DNA sequence analysis, whereas class II genes are identified primarily by DNA typing. Several potential combinations of donor/recipients may be identified, including syngeneic (twins), genotypically matched siblings (haploidentical), phenotypically matched family members or unrelated donors, and various degrees of mismatch (1, 2, or 3-antigen). Minor mismatches as well as partial matches based on GVHD and rejection vectors may also be identified. Because only 25–30% of patients have an HLA-identical sibling, identification of phenotypically matched unrelated donors is more feasible using large unrelated donor registries (>7 million donors have been typed worldwide). In the United States, the National Marrow Donor Program has typed nearly 5 million volunteer donors and uses 350 network centers to add 40,000 potential new donors each month. The chance of identifying an unrelated donor for a given individual is 20–67%, depending on the ethnic/HLA background. Transplants using one-antigen mismatched, unrelated donors are

possible if the mismatch is an allelic mismatch or very closely related HLA antigens.

In an effort to expand the pool of available unrelated donors, umbilical cord blood was found to be an excellent source of hematopoietic stem cells, allowing a greater degree of mismatch (1, 2, or 3 antigen), thus increasing the likelihood of finding a donor and a reduced incidence of GVHD at the cost of a longer time to engraftment. After delivery of an infant and clamping of the cord, 40–200?mL of umbilical cord blood is collected aseptically and stored. Numerous cord blood banks both public and private have been established around the world where cord blood can be donated or stored for potential personal use; more than 30,000 cord units have been made available for transplantation and more than 1,300 umbilical cord blood transplants (CBT) have been performed for nearly every indication for which SCT and peripheral blood stem cell transplantation (PBSCT) has been performed. The overall survival has been 30–65% for both related and unrelated CBT. Immune reconstitution after CBT appears to be complete with normal NK cell function, immunoglobulin production, and B- and T-cell repertoires. Both allogeneic related and unrelated PBSCT have the advantage of earlier engraftment and lower transplant morbidity but at the cost of increased chronic GVHD. Selection of an appropriate stem cell source depends on the patient's clinical status, HLA typing, and availability of adequate numbers of stem cells for engraftment.

Graft failure and graft rejection are influenced by several factors (Box 126–1); HLA disparity is the most important variable. Failure to engraft may occur in autologous as well as allogeneic SCT and may result from an inadequate stem cell dose or from marrow stromal damage by prior therapy in conjunction with the transplant preparative regimen. Graft rejection may occur immediately, without any increase in cell counts, or may follow a brief period of engraftment. Rejection is usually mediated by residual host T cells, cytotoxic antibodies, or lymphokines and is manifested by a fall in donor cell counts with a persistence of host lymphocytes. SCT using marrow from HLA disparate donors increases the risk for graft rejection and failure significantly. For example, the risk of graft failure in an HLA-identical

sibling SCT is 1–2%, whereas in haploidentical SCT the risk is 3–15%. Alloimmunization by exposure to multiple transfusions before SCT may sensitize the patient to HLA antigens, increasing the potential for graft rejection; this is observed most often with aplastic anemia. Because adequate immunosuppression of the host before marrow infusion is required to ensure engraftment and prevent rejection, the incidence of rejection depends in part on the conditioning regimen. With matched sibling SCT for aplastic anemia, there is a 24% incidence of graft rejection when cyclophosphamide is used alone as a preparative regimen compared with 3% when antithymocyte globulin is added. Post-transplant immunosuppression is useful to prevent GVHD and to minimize the likelihood of graft rejection. One effective approach to GVHD is to eliminate T cells from the donor marrow before infusion, but elimination of T cells allows the persistence of host lymphocytes, which are capable of mediating graft rejection in about 10% of cases. Graft rejection may be difficult to differentiate from the effects of drugs or viral infections on the graft. **REFERENCES**

Chapter 127 - Graft Versus Host Disease (GVHD)

Engraftment by donor lymphocytes in an immunologically compromised host (congenital, irradiation, or chemotherapy-induced immune defects) can result in donor T-cell activation against host major histocompatibility complex (MHC) antigens, with resultant GVHD. Cell death results from cell-mediated cytotoxic activity (e.g., natural killer cells) and a complex cascade of lymphokines released by activated lymphocytes (e.g., tumor necrosis factor [TNF]). For this reaction to occur, the graft must contain immunocompetent cells, the host must be immunocompromised and unable to reject or mount a response to the graft, and there must be histocompatibility differences between the graft and the host.

GVHD is classified as **acute GVHD,** occurring 100 days or less after stem cell transplantation (SCT), and **chronic GVHD,** occurring more than 100 days after SCT. GVHD can produce a **graft versus leukemia (GVL)** effect resulting in a lower relapse rate in patients transplanted for leukemia. This concept is the driving goal in nonmyeloablative SCT for malignancies by using low-dose or nonmyeloablative conditioning regimens with enough immune suppression to allow engraftment of donor cells, which then effect an antitumor alloreactive response. The process of GVHD represents a loss of “tolerance” normally maintained by thymic elimination of alloreactive lymphocytes; modulation of the T-cell receptor, rendering alloreactive cells anergic; and active suppressor cells that hold activated T cells in check.

Acute GVHD.

The acute form of GVHD is set up by release of inflammatory cytokines (e.g., interferons, interleukins, TNF) from damaged cells induced by the conditioning regimen. Host antigen presenting cells (APCs) present MHC-bound host-derived foreign antigens to infused donor T cells in an environment rich in cytokines, resulting in activation and proliferation of donor T cells. Activated donor CD4 and CD8 release additional cytokines, often referred to as a “cytokine storm,” to activate effector cytotoxic T cells and NK cells with resultant tissue damage. Clinically, acute GVHD is characterized by erythroderma, cholestatic hepatitis, and enteritis (Table 127–1). Typically, acute GVHD presents as the patient is starting to engraft. It usually starts with a pruritic macular/papular rash on the ears, palms, and soles and may progress to involve the trunk (Fig. 127–1) and extremities, potentially becoming a more confluent erythroderma with bullae formation and exfoliation. Fever may or may not be present. Other diagnostic considerations include toxicity from the preparative regimen, drug rash, and viral or other infectious exanthems. Hepatic manifestations include cholestatic jaundice with elevated liver function tests. The differential diagnosis includes hepatitis, veno-occlusive disease, or drug effect. The intestinal symptoms of acute GVHD include crampy abdominal pain and watery

diarrhea, often with blood. The conditioning regimen and infectious agents may produce similar symptoms. Eosinophilia, lymphocytosis, protein-losing enteropathy, bone marrow aplasia (neutropenia, thrombocytopenia, anemia), peripheral edema, and secondary infections may ensue. Factors related to the development of acute GVHD include histocompatibility differences between the

donor and patient, gender mismatching, donor parity, age, active or relapsed malignancy at the time of BMT, and increasing doses of radiation. The prevention and treatment of GVHD requires various immunosuppressive agents (see Chapter 128). A similar and potentially fatal acute GVHD can occur after transfusion of blood products to individuals who are relatively immunosuppressed, including patients post transplant, those receiving immunosuppressive cancer therapy, those who are HIV positive, those with congenital immunodeficiencies, and preterm infants. All cellular blood products for these patients

Figure 127-2 Chronic graft versus host disease of the skin with sclerodermoid changes. (Courtesy of Evan Farmer, MD.)

should be irradiated (2,500–5,000?cGy), but frozen acellular products such as fresh frozen plasma or cryoprecipitate do not need to be irradiated.

Chronic GVHD.

The maturation of the graft may include the development of chronic GVHD, usually after day 100 but as early as day 60. The probability of developing chronic GVHD in children is 24% after HLA-matched sibling SCT and 37% after matched unrelated donor SCT. The pathogenesis of chronic GVHD is poorly understood, but it appears to involve alloreactive donor T cells along with T-cell precursors that have become autoreactive resulting from aberrant thymic processing. Chronic GVHD resembles a multisystem autoimmune process mimicking elements of Sjögren (sicca) syndrome, systemic lupus erythematosus, and scleroderma (Fig. 127–2), lichen planus, bronchiolitis obliterans, and primary biliary cirrhosis. Recurrent infections (e.g., sepsis, sinusitis, pneumonia) with encapsulated bacteria and fungal and viral organisms are common and contribute significantly to transplant-related morbidity and mortality. Prophylaxis with trimethoprim-sulfamethoxazole reduces the incidence of *Pneumocystis carinii* pneumonia. Risks for chronic GVHD include increasing age (donor or host), prior acute GVHD, donor lymphocyte infusions, and a high level of parity of a female donor. Therapy for chronic GVHD consists of additional immunosuppression with agents (prednisone and cyclosporine are front-line drugs) described in Chapter 128 , again with the disadvantage of putting the patient at risk for infectious complications. Extensive skin involvement, thrombocytopenia (platelets < 100,000/µL), and progressive onset at diagnosis tend to predict a poor outcome.

Chapter 128 - Principles of Immunosuppression

Immunosuppressive agents are used to prevent and treat allograft rejection and graft versus host disease (GVHD). Because differences in major or minor histocompatibility antigens induce recipient T-lymphocyte activation and subsequent donor allograft rejection, immunosuppression is needed for all tissue transplantation, except from identical twins and certain instances of stem cell transplantation (SCT) for severe immunodeficiencies. Solid organ transplantation requires lifelong immunosuppression to prevent graft rejection (see Chapters 349 , 435 , and 528), whereas SCT recipients are treated for 6–12 mo until a state of tolerance is attained. Transplant strategies using selected stem and T cells to enhance engraftment but avoid GVHD and more potent immunosuppressive agents permit successful SCT across greater degrees of mismatched HLA antigens. The ideal immunosuppressive agent inhibits the host lymphocyte subsets that mediate rejection and inhibits donor lymphocytes that mediate GVHD without altering immunity against infection or malignancy (graft versus leukemia [GVL]).

Preparative Regimen.

Different preparative regimens are used for SCT for different diseases. Most agents have antineoplastic as well as immunosuppressant activity. Cyclophosphamide (and its isomer ifosfamide) is a nitrogen mustard derivative that requires metabolic activation to generate a bifunctional alkylating metabolite and is the most widely used immunosuppressant in SCT preparative regimens. Total body irradiation (TBI) is also an important therapeutic agent, with excellent antineoplastic activity and immunosuppressive qualities that can effectively treat all parts of the body. Other chemotherapeutic agents that have greater antitumor effects than immunosuppression have been used in combination with TBI and cyclophosphamide and include busulfan, etoposide, melphalan, carmustine (BCNU), cytarabine, thiotepa, and carboplatin. The combinations are designed to achieve adequate immunosuppression, allowing rapid engraftment without excessive toxicity and with the capacity to eliminate a malignant clone. Lower doses of these agents in conjunction with fludarabine have been used in nonmyeloablative SCT to result in a 90–100% engraftment, but GVHD remains a problem; it is still too early to know whether GVL will achieve similar results to conventional high-dose therapy. A nonmyeloablative approach may be most useful in nonmalignant disorders where the presence of normal donor cells (graft) is corrective for the disorder.

T-Cell Depletion.

Prevention of graft rejection and GVHD along with treatment of GVHD in the peritransplant period involves several different strategies. Because donor T cells are responsible for GVHD, donor marrows have been depleted of T cells using monoclonal antibodies or physical separation techniques such as soy lectin agglutination. Depletion results in a dramatic reduction in GVHD but can cause graft rejection and relapse. Donor T cells have an important role in eliminating residual host T cells as well as in mediating a GVL effect. Alternatives to T-cell depletion are being explored, including adding back-selected T cells that may help engraftment and retain antitumor activity but without GVHD activity.

Methotrexate.

This competitive inhibitor of dihydrofolate reductase is an excellent immunosuppressive agent, in addition to being a cancer chemotherapeutic drug. A regimen of methotrexate given on days 1, 3, 6, and 11 post transplant is effective at preventing GVHD, with additional improvement when used in conjunction with cyclosporine. Methotrexate may aggravate mucositis resulting from the conditioning regimen and may require rescue with leucovorin if a patient has renal impairment or a fluid collection, such as a pleural effusion. Trimetrexate is an antifolate drug with structural similarity to methotrexate, but it is eliminated by the liver and may be an alternative for patients who have significant renal impairment.

Cyclosporine.

Cyclosporine is a lipophilic (hydrophobic), cyclic, 11-amino acid peptide that is a potent and specific immunosuppressive agent that blocks T-cell activation by interfering with the T-cell receptor–mediated signal cascade to selectively inhibit the transcription of interleukin (IL)-2. Cyclosporine may also inhibit IL-1, IL-3, and interferon-? synthesis. Cyclosporine inhibits IL-2 receptor formation at higher doses. Although cyclosporine has no myelosuppressive or anti-inflammatory effects beyond its effects on T cells, it is very useful for preventing graft rejection. Cyclosporine is metabolized by the hepatic cytochrome P450 enzyme system and can be involved in a number of drug interactions. Cyclosporine levels increase in the presence of ketoconazole, erythromycin, warfarin, verapamil, ethanol, imipenem-cilastatin, metoclopramide, itraconazole, and fluconazole. These levels decrease in the presence of phenytoin, phenobarbital, carbamazepine, valproate, nafcillin, octreotide, trimethoprim, and rifampin.

Cyclosporine has significant nonimmunosuppressant adverse effects, including the following: neurotoxicity (tremors, paresthesias, headache, confusion, somnolence, seizures, coma), hypertrichosis, gingival hyperplasia, anorexia, nausea, vomiting, hepatotoxicity (cholestasis, cholelithiasis, hemorrhagic necrosis), endocrinopathies (ketosis, hyperprolactinemia, hypertestosteronism, gynecomastia, impaired spermatogenesis), metabolic disorders (hypomagnesemia, hyperuricemia, hyperglycemia, hyperkalemia, hypocholesterolemia), vascular derangements (hypertension, increased sympathetic nervous system activation, vasculitic-hemolytic uremic syndrome–like illness, atherogenesis), and nephrotoxicity. Renal toxicity is a significant limitation of cyclosporine use and is manifested as an increased creatinine

level, oliguria, hypertension, fluid retention, vasoconstriction of the afferent glomerular filtration rate, renal tubular damage, and hemolytic-uremic syndrome–like lesions. Chronic nephrotoxicity (interstitial fibrosis, tubular atrophy) may require a reduction of the cyclosporine dose or a change to other immunosuppressant drugs. Nephrotoxicity may be exacerbated by aminoglycosides, amphotericin B, acyclovir, digoxin, furosemide, indomethacin, or trimethoprim. The renal toxicity may be reduced by adjusting dosing based on blood cyclosporine levels. Levels may also be influenced by clinical conditions affecting absorption, including diarrhea, intestinal disorders (due to GVHD, viral infections, or therapy), or altered hepatic function. Although the drug is lipophilic, obesity does not influence the distribution of the drug and dosing should be based on ideal body weight. Cyclosporine is as effective as methotrexate for post-SCT immunosuppression, and the combination of cyclosporine with methotrexate is better than treatment with either drug alone.

Tacrolimus.

Tacrolimus is a macrolide immunosuppressive drug produced by the fungus *Streptomyces tsukubaensis* that is chemically distinct from cyclosporine but with similar effects on the immune system. Although it binds specific proteins, it has the same effects on the expression of IL-2 and the IL-2 receptor as cyclosporine. Tacrolimus has little advantage over cyclosporine, except possibly for the treatment of GVHD of the liver because it is concentrated in the liver. The toxicities and drug interactions are similar to those of cyclosporine. The combination of these drugs causes synergistic toxicity.

Corticosteroids.

Prednisone, usually in combination with other immunosuppressive agents, is often used to treat or prevent GVHD and to prevent rejection. Corticosteroids may interfere with T-lymphocyte proliferation by blocking activation of IL-1 and IL-6 through induction of soluble IL-receptor antagonists. Because IL-2 secretion depends in part on IL-1 and IL-6 release, corticosteroids block IL-2 action indirectly. Corticosteroids also produce a more rapid anti-inflammatory response by inducing the production of lipocortin, an inhibitor of phospholipase A_2 , which reduces the synthesis of inflammatory prostaglandins. They may also lyse small populations of activated lymphocytes and reduce the migration of monocytes to sites of inflammation. Nonspecific and pronounced immunosuppressant effects of corticosteroids (and other immunosuppressants) place the patient at risk for serious opportunistic infections. Other long-term complications of corticosteroid use include growth failure, cushingoid appearance, hypertension, cataracts, gastrointestinal bleeding, pancreatitis, psychosis, hyperglycemia, osteoporosis, aseptic necrosis of the femoral head, and suppression of the pituitary-adrenal axis.

Antibodies.

Antithymocyte globulin (ATG) is a preparation of heterologous antibodies against human thymocytes that have been generated from horses, rabbits, and other sources. These antibody preparations are potent immunosuppressants and have been useful in preparative regimens as well as for treatment of resistant GVHD. Toxicities include fever, hypotension, rash-urticaria, tachycardia, dyspnea, chills, myalgias, serum sickness, and potential anaphylaxis. Diphenhydramine, acetaminophen, and hydrocortisone help to minimize side effects.

Other antibodies such as **anti-CD33 (gemtuzumab ozogamicin)** or **anti-CD20 (rituximab)** alone or conjugated to cytotoxins function to target not only specific immune cellular components but also malignant cells expressing these proteins. These antibody preparations have been used to treat relapsed disease with resultant complete remissions and are now being used in conjunction with conventional preparative regimens. Rituximab is the treatment of choice for post-transplant Epstein-Barr virus–driven lymphoproliferative disease. Anticytokine antibodies (tumor necrosis factor, IL-1, interferon-?) block the cytokine cascade and have shown promising results in early trials to treat refractory GVHD.

Thalidomide.

Initially used as a sedative but found to have immunosuppressive properties, thalidomide has been studied in phase I–II trials for treating patients with high-risk or refractory chronic GVHD; it has shown a 59% response rate with a 76% survival for those with refractory chronic GVHD and 48% for those with high-risk chronic GVHD. Phase III treatment trials have found poor tolerance of higher doses requiring dose modification, whereas prevention trials have demonstrated thalidomide to be ineffective for prevention of chronic GVHD.

Chapter 129 - Late Effects of Stem Cell Transplantation

As more children are undergoing stem cell transplantation (SCT) for a widening spectrum of indications and an increasing number of these children become long-term survivors, late effects of the transplant process have a lasting impact on the health and well-being of the individual. Possible delayed complications include effects on growth and development, neuroendocrine dysfunction, fertility, second tumors, chronic graft versus host disease (GVHD), cataracts, leukoencephalopathy, and immune dysfunction.

Neurologic Function.

Infections, metabolic encephalopathy (resulting from hepatic dysfunction), and drug and irradiation (radiotherapy) all may contribute to neurologic sequelae. Cyclosporine may produce headache, which is usually responsive to propranolol, as well as tremor, confusion, visual disturbance, seizures, and frank encephalopathy. Most of these adverse effects are reversible with discontinuation of the drug.

Leukoencephalopathy is a clinical syndrome characterized by lethargy, slurred speech, ataxia, seizures, confusion, dysphagia, and decerebrate posturing. It may present as minimal symptoms or can result in coma or death in its most severe form. MRI and CT reveal multifocal areas of white matter degeneration with necrosis. Leukoencephalopathy is observed almost exclusively in patients who have received extensive intrathecal chemotherapy or cranial irradiation before transplantation, with an overall incidence of 7% among these patients.

The incidence of cataracts is approximately 80% in patients receiving single-dose total body irradiation (800–1,000?cGy TBI), 20–50% with fractionated TBI, and 20% after regimens with only chemotherapy. A dry eye syndrome, or keratoconjunctivitis sicca, is often related to chronic GVHD and is treated with artificial tears and lubricants.

Secondary Malignancies.

The overall risk of developing a secondary form of cancer is six to eight times that in the general population, with the greatest risk being within the 1st yr. Approximately half of the secondary tumors in the 1st year are non-Hodgkin's lymphomas, and two thirds of these are positive for Epstein-Barr virus (EBV). In a study of 3,182 children transplanted for leukemia from 1964–1992, 25 solid tumors developed compared with an expected single case in the general population, with most of the tumors (n =

14) being thyroid and brain tumors. Risk factors that are associated with second malignancies include the diagnosis of immunodeficiency, use of antithymocyte globulin (ATG), T-cell depletion of the donor marrow, younger age at the time of transplant, and TBI in the preparative regimen. EBV-related B-cell lymphomas, which are aggressive and resistant to most therapeutic interventions, have been successfully treated with infusions of donor T cells or anti-CD20 antibody.

Growth.

Long-term follow-up studies of patients who have received TBI-containing regimens reveal significant growth depression and growth hormone deficiency, which can diminish adult height. Patients 8 yr after treatment with TBI are 1–2 standard deviations (SD) below the mean height for age, which further decreases to 1.5–3 SD if cranial irradiation was added to TBI. This decrease in growth velocity is similar for boys and girls. Fractionation of irradiation results in less impact (1 SD below the mean height for age) on height compared with single-dose TBI

(2 SD below mean height for age). Children receiving radiation-containing regimens also have no pubertal growth spurt, which depends on the presence of adequate growth hormone and gonadal hormones, both of which may be low after transplantation. A major determinant of adult height is the amount of growth before puberty. A study of 175 children younger than 6 yr of age, 6–12 yr of age, or 12–15 yr of age receiving TBI-based regimens and not treated with growth hormone reported a mean final adult height of 3.49, 1.92, and 0.37 SD below average, respectively. Chronic GVHD and its treatment with corticosteroids may also contribute to growth impairment after transplant. In an attempt to avoid TBI-related growth effects in children, chemotherapy-only regimens such as busulfan/cyclophosphamide have been used. Growth studies indicate that busulfan has much less of an impact on growth but produces the same gonadal failure as TBI-based regimens. Preparative regimens using only cyclophosphamide for aplastic anemia have little effect on normal growth and development. Irradiation of the long bones and vertebral bodies for neuroblastoma also contributes to decreased growth velocity. Therapy with recombinant growth hormone after age 12 yr prevents a further decrease in growth velocity, but little or no catch-up growth is achieved.

Annual growth hormone evaluation is essential for all children after SCT. Current studies are aimed at identifying children with growth hormone deficiencies at an earlier age and administering supplemental growth hormone to achieve a normal pubertal growth spurt. Gonadal hormones are essential for normal pubertal growth as well as development of secondary sexual characteristics. Approximately 75% of patients receiving TBI-containing regimens show delayed development of secondary sexual characteristics, resulting from primary ovarian or testicular failure. Laboratory evaluation reveals elevated follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels with depressed estradiol and testosterone. These patients require careful follow-up with evaluation of annual Tanner scores and endocrine function. Supplementation of gonadal hormones is useful for primary gonadal failure and is given along with growth hormone to promote pubertal growth.

Thyroid Function.

The use of TBI with or without additional conventional irradiation involving the thyroid gland may result in hypothyroidism. Some children who have received single-dose TBI develop compensated (28–56%) or overt (9–13%) hypothyroidism. The use of fractionated TBI has significantly reduced the incidence of both compensated (10–14%) and overt (<5%) hypothyroidism. Risk factors for the development of hypothyroidism appear to be related only to the use of irradiation, with no influence of age, sex, or GVHD. The site of injury by irradiation is at the level of the thyroid gland rather than at the pituitary or hypothalamus. Therapy with thyroxine is very effective for overt hypothyroidism, but treatment of compensated hypothyroidism is more controversial. Despite treatment of hypothyroidism, there remains a risk for thyroid carcinoma. Because the risk of hypothyroidism continues for many years, annual thyroid function studies are important. Chemotherapy-only preparative regimens have far fewer effects on normal thyroid function.

Immune Reconstitution.

Chemoradiotherapy for SCT results in complete eradication of host B- and T-cell immunity. After infusion of donor marrow, recovery of the normal immune functions takes many months or years. The ability of newly engrafting B cells to respond to mitogenic stimulation is intact by 2–3 mo. Because the production of antibodies requires B- and T-cell interaction, normal IgM levels are not observed until 4–6 mo after transplant; IgG levels take 7–9 mo to normalize, and it may take 2 yr before normal IgA levels are achieved. T-cell recovery also takes many months. CD8 T cells recover by about 4 mo, but CD4 T cells do not increase until 6–9 mo, resulting in an inverted CD4/CD8 ratio for the first 6–9 mo after transplant. Factors that prolong this interval include T-cell depletion of the marrow, post-transplant immunosuppression, and chronic GVHD. Patients with chronic GVHD have a continued decrease in the number of cytotoxic T lymphocytes and helper T cells, along with increased suppressor T cells.

Live virus vaccines should be avoided in immunocompromised patients. Reimmunization of an individual will be successful only after adequate recovery of immune function. For patients without chronic GVHD, diphtheria and tetanus toxoids, acellular pertussis (in children <7 yr of age), inactivated polio, hepatitis B, *Haemophilus influenzae* type b, and *Streptococcus pneumoniae* immunizations may be given 12 mo after transplant, and measles-mumps-rubella immunizations after 24 mo. Influenza vaccines should be given every fall. If chronic GVHD is present, re-immunization should be postponed and IgG supplemented until it resolves.

Part 14 - Allergic Disorders

Chapter 130 - Allergy and the Immunologic Basis of Atopic Disease

Donald Y. M. Leung

Allergic diseases such as asthma, food allergy, atopic dermatitis, and allergic rhinitis are common illnesses that have been increasing in prevalence during the past 30 years. The term ***allergy*** was first coined, in 1906, by von Pirquet, who used it to refer to patients who expressed an “altered state of reactivity” to common environmental antigens. With the discovery, in the late 1960s, that most patients with allergy produce IgE antibodies to antigens that trigger their illness, the term *allergy* is often used interchangeably with clinical expression of IgE-mediated allergic disease. This is an oversimplification of the mechanisms involved in allergic disease because a subset of individuals with asthma, atopic dermatitis, and allergic rhinitis have non–IgE-mediated disease despite manifesting eosinophilia and mast cell activation. Furthermore, certain allergic diseases, such as contact dermatitis, are primarily T cell–mediated without evidence of IgE responses to environmental triggers.

Atopy is derived from the Greek *atopos*, meaning “out of place,” and often used to describe patients with IgE-mediated diseases. Such individuals have a familial predisposition to allergic diseases, which are manifest as hyperresponsiveness in their target organs (e.g., the lung, skin, or nose). Importantly, this hyperresponsiveness has both IgE-mediated and non–IgE-mediated inflammatory components, which lowers the threshold of the target organ to subsequent allergen exposure.

FEATURES OF ALLERGIC DISEASES

Allergens.

The term ***allergen*** refers to an antigen that triggers an IgE response in genetically predisposed individuals. Most allergens are proteins that have molecular weights of 10–70?kd; molecules smaller than 10?kd would not bridge adjacent IgE antibody molecules on the surface of mast cells or basophils, and most molecules larger than 70?kd would not pass through mucosal surfaces needed to reach antigen-presenting cells for stimulation of the immune system. Allergens frequently function in their natural state as proteolytic enzymes, which may contribute to increased mucosal permeability and sensitization. Many major allergens have been identified and cloned, including Der p 1 and Der p 2 from the house-dust mite (*Dermatophagoides pteronyssinus*), Fel d 1 from cat, and a number of tree, grass, and weed pollens, including Bet v 1 from birch tree, Phl p 1 and Phl p 5 from timothy grass, and Amb a 1, 2, 3, and 5 from giant ragweed.

Type 2 Helper T Cells.

All individuals are exposed to potential allergens. Nonatopic subjects respond with the proliferation of T helper type 1 (Th1) cells, which secrete cytokines, including interferon (IFN)-?, that are involved in the elicitation of allergen-specific IgG antibodies. Th1 cells are generally involved in the eradication of intracellular organisms such as mycobacteria (Fig. 130–1), because of the ability of Th1 cytokines to activate phagocytes and promote the production of opsonizing and complement-fixing antibodies. However, genetically predisposed atopic individuals respond with a brisk expansion of T helper type 2 (Th2) cells that secrete cytokines favoring IgE synthesis and are involved in host defense against extracellular organisms such as parasites.

Atopic responses include the generation of allergen-specific IgE antibodies that are detectable by serum testing or positive immediate reactions to allergen extracts on prick skin testing (see Chapter 131). The Th2 cytokines interleukin (IL)-4 and IL-13 play a key role in immunoglobulin isotype switching to IgE (Fig. 130–2). IL-5 and IL-9 further enhance IgE synthesis and play an important role in the differentiation and development of eosinophils. The combination of IL-3, IL-4, and IL-9 contributes to mast cell development. Thus, Th2 cytokines have been proposed to play an important role in the pathogenesis of asthma and allergic diseases. This is supported by the observation that Th2 cells infiltrate into the affected tissues of acute allergic tissue reactions. Interesting, chronic allergic reactions often are characterized by the infiltration of Th1 and Th2 cells. This is important because Th1-type cytokines such as IFN-? can potentiate the function of allergic inflammatory effector cells such as eosinophils and thereby contribute to disease severity.

In utero, T cells of the fetus are primarily of the Th2 type, which reduces reactivity of the maternal immune system against the fetal allograft. Postnatally, the nonatopic infant's immune system shifts to a Th1-mediated response to environmental allergens, whereas the atopic infant has a further increase in Th2 cells that were potentially primed in utero by transplacental exposure to allergens. Microbes are the major stimulus for Th1-mediated immunity. Macrophages or dendritic cells stimulated by microbial products, such as endotoxin, secrete IL-12, which is an important inducer of Th1 cells. Because Th1 cells inhibit Th2 cell development, factors that contribute to Th1 cell development reduce allergic responses. High-affinity interactions between T cells and antigen-presenting cells, large amounts of antigen, Th1 cytokines (IL-12 and IL-18), and exposure to microbial DNA containing cytidine-phosphate-guanosine (CpG) repeats are all factors that favor the Th1 phenotype. In contrast, exposure to Th2 cytokines (IL-4), prostaglandin E_2 (PGE_2), nitric oxide, low-affinity interactions between T cells and antigen-presenting cells (APCs), and small amounts of antigen are factors favoring the Th2 phenotype.

Antigen-Presenting Cells.

Dendritic cells, Langerhans cells, monocytes, and macrophages play an important role in the induction of allergic inflammation by presenting allergens to T cells and by contributing to the local recruitment of effector cells. APCs are a heterogeneous group of cells with the common property of presenting antigens in the context of the major histocompatibility complex (MHC). Of the various professional APCs, dendritic cells and Langerhans cells are unique in their ability to prime naïve T cells and are thus responsible for the primary immune response, that is, the sensitization phase of allergy. APCs are found primarily in lymphoid organs and the skin. Monocytes and macrophages likely play more of a role in activating memory T-cell responses, the elicitation phase of allergy.

Dendritic cells residing in peripheral sites such as the skin, intestinal lamina propria, and lung are relatively immature. These cells are actively phagocytic but express fewer MHC and

---

Figure 130-1 T-cell differentiation.

co-stimulatory molecules than mature APCs. These immature dendritic cells take up antigens in tissues and then migrate to the T-cell areas in locally draining lymph nodes. During this migration, they undergo phenotypic and functional changes characterized by increased expression of MHC class I, MHC class II, and co-stimulatory molecules that react with CD28 expressed on T cells. In the lymph nodes, they directly present processed antigens to resting T cells to induce their proliferation and differentiation.

Based on their ability to favor Th1 or Th2 differentiation, mature dendritic cells have been called DC1 or DC2, respectively. The critical factor for the polarizing mechanism to Th1

Figure 130-2 Role of Th2 cytokines in allergic cascade.

cells is the level of IL-12 produced by DC1 cells. In this regard, a cytokine such as IFN-? is a potent DC1-promoting factor. Differentiation of T cells in the absence of IL-12 production by DC2 leads to Th2 cells. Histamine and PGE_2 inhibit IL-12 production and contribute to the development of DC2. A unique feature of atopy is

the presence of allergen-specific IgE on the cell surface of their APCs. Importantly, the formation of Fc e receptor I (FceRI)/IgE/allergen complexes on the APC cell surface markedly facilitates allergen uptake and allergen presentation. The clinical importance of this phenomenon is supported by the observation that FceRI-positive Langerhans cells bearing IgE molecules is a prerequisite for provocation of eczematous lesions by aeroallergens applied to the skin of patients with atopic dermatitis. The role of the low-affinity IgE receptor Fc e receptor II (FceRII, CD23) on monocyte-macrophages is less clear, although it appears that under certain conditions it can also facilitate antigen capture; and cross-linking of this receptor as well as FceRI on monocyte-macrophages can lead to the release of inflammatory mediators.

IgE and Its Receptors.

The acute allergic response is dependent on IgE and its ability to bind selectively to the alpha chain of the high-affinity FceRI or the low-affinity FceRII. Cross-linking of receptor-bound IgE molecules by allergen initiates a complex intracellular signaling cascade followed by mast cell or basophil degranulation and the release of various mediators of allergic inflammation. The FceRI molecule is also found on the surface of antigen-presenting dendritic cells (e.g., Langerhans cells) but differs from the structure found on mast cells/basophils in that the FceRI molecule found on dendritic cells lacks the ß chain. CD23 is found on mononuclear cells, eosinophils, platelets, and follicular dendritic cells.

The induction of IgE synthesis involves two major signals. The initial signal involves activation of germline transcription at the e immunoglobulin locus by IL-4 or IL-13, and thus dictates isotype specificity. The second signal involves the engagement of CD40 on B cells by CD40 ligand expressed on T cells. This leads to activation of the recombination machinery, resulting in DNA switch recombination. CD40 engagement can be replaced as a second signal by Epstein-Barr virus infection or glucocorticoid treatment. Interactions between several pairs of co-stimulatory molecules (CD28/B7, LFA-1/ICAM-1, and CD2/CD58) can further amplify signal 1 and signal 2 to enhance IgE synthesis. Factors that inhibit IgE synthesis include Th1-type cytokines

(IL-12, IFN-a and IFN-?) and microbial DNA containing CpG repeats.

Eosinophils.

Allergic diseases are characterized by peripheral blood and tissue eosinophilia. Eosinophils contain dense intracellular granules that are sources of inflammatory proteins. These include major basic protein, eosinophil-derived neurotoxin, peroxidase, and cationic protein. Eosinophil granule proteins have been found to damage epithelial cells, induce airway hyperresponsiveness, and cause degranulation of basophils and mast cells. Major basic protein released from eosinophils can bind to an acidic moiety on the M2 muscarinic receptor and block its function, thereby leading to increased acetylcholine levels and the development of increased airway hyperreactivity. The eosinophil is also a rich source of leukotrienes, particularly cysteinyl leukotriene C4, which contracts airway smooth muscle and increases vascular permeability. Other secretory products of eosinophils include cytokines (IL-4, IL-5, TNF-a), proteolytic enzymes, and reactive oxygen intermediates, all of which can significantly enhance allergic tissue inflammation.

Several cytokines regulate the function of eosinophils in allergic disease. Eosinophils develop and mature in the bone marrow from IL-5–responsive precursor cells. Allergen challenge of clinically allergic patients causes resident bone marrow CD34 cells to express the IL-5 receptor, which stimulates eosinophils to synthesize granule proteins, prolongs their survival, potentiates degranulation of eosinophils, and stimulates the release of eosinophils from the bone marrow. Granulocyte-macrophage colony-stimulating factor (GM-CSF) also enhances proliferation, cell survival, cytokine production, and degranulation of eosinophils. Certain chemokines such as RANTES, macrophage inflammatory protein 1a (MIP-1a), and eotaxins, play an important role in attracting eosinophils into local allergic tissue inflammatory reactions. In particular, eotaxins mobilize IL-5–dependent eosinophil colony-forming progenitor cells from the bone marrow. These progenitors are rapidly cleared from the blood and either return to the bone marrow or are recruited to inflamed tissue sites.

Mast Cells.

Mast cells are derived from CD34 hematopoietic progenitor cells that arise in the bone marrow, enter the circulation, and travel to peripheral tissue where they undergo tissue specific maturation. Interactions between the tyrosine kinase receptor c-*kit* expressed on the surface of mast cells and the fibroblast-derived c-*kit* ligand, stem cell factor (SCF), are essential for mast cell development and survival. Unlike mature basophils, mature mast cells do not usually circulate in the blood but are widely distributed throughout connective tissues, where they often lie adjacent to blood vessels and beneath epithelial surfaces that are exposed to the external environment, such as the respiratory tract, gastrointestinal tract, and skin. Thus, mast cells are positioned anatomically to participate in allergic reactions. There are at least two subpopulations of human mast cells: mast cells with tryptase and mast cells with both tryptase and chymase. Mast cells with tryptase are the predominant type found in the lung and small intestinal mucosa, whereas mast cells with both tryptase and chymase are the predominant type found in the skin, gastrointestinal submucosa, and blood vessels.

Mast cells contain or produce on appropriate stimulation a diverse array of mediators that can have different effects on allergic inflammation and organ function. These include preformed granule-associated mediators (e.g., histamine, serine proteases, and proteoglycans) and de novo synthesis and release of membrane-derived lipids, cytokines, and chemokines. The most important mast cell–derived lipid mediators are the cyclo-oxygenase and lipoxygenase metabolites of arachidonic acid, which have potent inflammatory activities. The major cyclo-oxygenase product of mast cells is prostaglandin D_2 , and the major lipoxygenase products are the sulfidopeptide leukotrienes: LTC_4 and its peptidolytic derivatives LTD_4 and LTE_4 . Mast cells also can produce cytokines, including those that promote Th2-type responses (IL-4, IL-13, GM-CSF) and inflammation (tumor necrosis factor [TNF]-a, IL-6) and regulate tissue remodeling (transforming growth factor, vascular endothelial cell growth factor). Immunologic activation of mast cells and basophils typically begins by cross-linkage of IgE bound to the FceRI with multivalent allergen. Cell surface FceRI on mast cells is increased by IL-4 and IgE. Of potential therapeutic interest, surface

levels of FceRI decrease in subjects receiving treatment with anti-IgE antibody that lowers serum IgE. Degranulation of mast cells can also occur via nonimmunologic stimuli such as multivalent lectins (concanavalin A), basic molecules such as compound 48/80, morphine, eosinophil-derived major basic protein, and substance P, and a variety of IgE-dependent and IgE-independent histamine-releasing factors secreted by mononuclear cells.

MECHANISMS OF ALLERGIC TISSUE INFLAMMATION

IgE-mediated immune responses can be classified chronologically according to three patterns of reaction. First, the **early phase response** is the immediate response after introduction of allergen into target organs typically results from mast cell degranulation accompanied by the release of preformed mediators, occurring within 10?min after allergen exposure and resolving within 1–3?hr. Acute reactions are associated with increased local vascular permeability leading to leakage of plasma proteins, tissue swelling, increased blood flow, as well as itching, sneezing, wheezing, and acute abdominal cramps in the skin, nose, lung, and gastrointestinal tract, respectively (depending on the target organ in which the allergen challenge takes place).

Second, a **late phase response** (LPR) can occur within hours of allergen exposure, reaching a maximum at 6–12?hr and resolving by 24?hr. Clinically, cutaneous LPRs are characterized by edema, redness, and induration; in the nose, by sustained nasal blockage; and in the lung, by additional wheezing. LPRs are associated with the early infiltration of neutrophils and eosinophils followed by basophils, monocytes and macrophages, and Th2-type cells. The recruitment of inflammatory cells from the circulation requires the upregulation of adhesion molecules on their cell surface and their ligand on endothelial cells, which are under the control of cytokines. Several hr after allergen exposure, TNF-a, which is released by activated mast cells, induces the endothelial expression of E-selectin and intercellular (ICAM-1) and vascular (VCAM-1) cell adhesion molecules, which leads to the transendothelial migration of various inflammatory cells. Preferential accumulation of eosinophils occurs through the interactions between selective adhesion molecules on the eosinophil (a4ß1 integrin or VLA-4) and VCAM-1 that can be further induced by IL-4 and IL-13 on endothelial cells.

Chemokines are chemotactic cytokines that play a central role in the directed migration of inflammatory cells. RANTES, macrophage inflammatory protein 1a, monocyte chemotactic protein (MCP)-3, and MCP-4 are chemoattractants for eosinophils and mononuclear cells, whereas the eotaxins are relatively selective for eosinophils. These chemoattractants have been detected in epithelium, macrophages, lymphocytes, and eosinophils at sites of LPR and allergic tissue inflammation. Blockage of their action leads to significant reduction in tissue-directed migration of allergic effector cells.

Third, in patients with chronic allergic disease, tissue inflammation can persist for days to years. Several factors contribute to persistent tissue inflammation, including recurrent exposure to allergens and microbial agents with repeated stimulation of allergic effector cells such as mast cells, basophils, eosinophils, and Th2 cells. Th2 type cytokines (IL-3, IL-5, and GM-CSF) secreted during allergic reactions can prolong the survival of allergic effector cells because of delayed apoptosis. There is

also evidence for local differentiation of tissue-infiltrating eosinophil precursors induced by IL-5 causing self-generation of eosinophils that contributes to continued damage of local tissue. Tissue remodeling leading to irreversible changes in target organs is also a feature of chronic allergic disease. In asthma, remodeling involves thickening of the airway walls, with increased submucosal tissue and smooth muscle and a decline in lung function with age. In atopic dermatitis, lichenification is an obvious manifestation of skin remodeling.

Studies indicate that Th2 cytokines can not only maintain allergic inflammation but also contribute to tissue remodeling by activating resident cells in target organs: IL-4, Il-9, and IL-13 can induce mucus hypersecretion and metaplasia of mucus cells; IL-4 and IL-13 stimulate fibroblast growth and synthesis of extracellular matrix proteins; and IL-5 and IL-9 increase subepithelial fibrosis. Subepithelial fibrosis can result from transforming growth factor-ß produced by eosinophils and fibroblasts. IL-11 expressed by eosinophils and epithelial cells also causes subepithelial fibrosis, enhanced deposition of collagen, and the accumulation of myofibroblasts and fibroblasts. Taken together, once the allergic immune response is established it can be self-perpetuating and lead to chronic disease in genetically predisposed individuals.

GENETIC BASIS OF ATOPY

Atopic diseases have a familial predisposition and a genetic basis. However, sorting out the key genes in multifactorial disorders such as asthma, atopic dermatitis, and allergic rhinitis in which environmental and genetic factors are important has been difficult. It is likely that clinical expression of these diseases results from the complex interaction of many genetic loci and that variation in each of these genes contributes to the diversity of phenotypes observed in each atopic disease. The situation is further complicated by the multiple markers that can overlap for various allergic diseases. For example, atopy is frequently defined by positive immediate prick skin tests and elevated serum IgE levels whereas asthma is characterized by airway hyperresponsiveness. Studies suggest that allergic diseases likely have at least two major groups of genes: genes that control systemic expression of atopy (e.g., increased IgE synthesis and eosinophilia) that are commonly expressed among various allergic diseases and genes that control local inflammatory responses in specific target organs (e.g., the skin in atopic dermatitis or the lung in asthma). For example, genome screens for atopic dermatitis have identified linkage on chromosomes 1q21, 3q21, 17q25, and 20p. These regions correspond closely with known psoriasis loci. The 1q21 locus is known to contain a cluster of genes influencing epidermal differentiation.

The major approaches used for identification of relevant genes in atopic diseases have included the candidate-gene approach, which depends on the identification of polymorphisms that alter the function or expression of genes known to control atopy or inflammation, and positional cloning, which links the inheritance of specific chromosomal regions with the inheritance of a disease. This is followed by physically mapping the target region to identify genes within it. Candidate genes are then screened for mutations and polymorphisms. Several candidate genes associated

with atopic diseases have been identified (Table 130–1). Linkage and strong association have been detected particularly to specific alleles on chromosomes 5, 6, 11, 12, and 14.

Chromosome 5.

The 5q23-35 region contains several genes implicated in the pathogenesis of allergic diseases. These include the genes coding for Th2 cytokines (IL-3, IL-4, IL-5, IL-9, IL-13, and GM-CSF). IL-4 has been particularly well studied as a potential candidate gene. A cytosine to thymidine exchange at position 589 of the IL-4 promoter region is associated with the formation of a unique binding site for the transcription factor, nuclear factor for activated T cells (NF-AT), increased IL-4 gene transcription, higher NF-AT binding affinity, and increased IgE production. This is consistent with the important role of IL-4 in the development of Th2 cells and immunoglobulin isotype switching to IgE synthesis. Other genes on this chromosome that may alter allergic responses include leukotriene C4 synthase, M-CSF receptor, the glucocorticoid receptor, and ß2-adrenergic receptor.

Chromosome 6.

This chromosome contains the genes that code for human leukocyte antigen (HLA) class I and class II molecules, which regulate the specificity and intensity of immune responses to specific allergens. It also includes genes that are central to the process of antigen recognition and presentation, including transporters associated with antigen processing (TAP). IgE responses to specific allergens such as ragweed antigen Amb a V and mite allergen Der p I have been linked to specific MHC class II loci. Of note, TNF-a, a key cytokine that contributes to the influx of inflammatory cells, is also located on chromosome 6. TNF-a polymorphisms have been associated with asthma.

Chromosome 11.

Several genome-wide searches have linked atopy to chromosome region 11q13. The gene encoding the ß subunit of the high-affinity IgE receptor (FceR1-ß), which amplifies signal transduction through the high-affinity IgE receptor, has been proposed to be the candidate gene in this

TABLE 130-1 -- **Chromosomal Regions and Candidate Genes in Atopic Disease**

Chromosome	Candidate Genes	Potential Function
1	IL-10	Anti-inflammatory cytokine
	IL-12 receptor	Induction of IFN-?
5q23-35	IL-3, IL-4, IL-5, IL-9, IL-13, GM-CSF	IgE synthesis and Th2 response
	Glucocorticoid receptor	Corticosteroid action
	Leukotriene C4 synthase	Leukotriene production
	ß$_2$ -Adrenergicreceptor	G protein–coupled ß$_2$ -agonist receptor
	M-CSF receptor	Inflammatory modulation
6p21-23	MHC, TAP-1, TAP-2; TNF-a	Antigen presentation; inflammatory cytokine
10q	5-Lipoxygenase	Leukotriene production
11q13	FceRI ß chain	Signal transduction in basophils, mast cells, and dendritic cells.
12q14-24	IFN-?; STAT-6; SCF	IL-4 inhibition; IL-4 signaling; mast cell development, proinflammatory enzyme
	Nitric oxide synthetase	
14q11-13	TCR a chains	Peptide MHC interaction
16q11-12	IL-4 receptor	IgE class switching, Th2 response
17p12-q11.2	RANTES, eotaxin	Chemokines

IL = interleukin; GM-CSF = granulocyte-macrophage colony-stimulating factor; M-CSF = macrophage colony-stimulating factor; IFN = interferon; SCF = stem cell factor; MHC = major histocompatibility complex;TAP = transporters involved in antigen processing and presentation; STAT = signal transducer and activator of transcription;TCR =T-cell receptor;TNF = tumor necrosis factor.

region. Several genetic variants of FceR1-ß have been associated with asthma, bronchial hyperreactivity, and atopic dermatitis.

Chromosome 12.

Linkage of chromosome 12 to asthma and atopy has been observed. Chromosome 12q contains several candidate genes (IFN-?, nitric oxide synthetase (NOS), stem cell factor (SCF), STAT-6, insulin-like growth factor-1, and the ß subunit of nuclear factor-Y (NFYB), which may contribute to the development of asthma. IFN-? promotes the development of Th1 cells and inhibits Th2 cell function. STAT-6 is activated by IL-4 and is involved in the induction of IgE isotype switching and Th2 cell differentiation. SCF supports the proliferation and differentiation of mast cells.

Other Chromosomes.

Chromosome 14 contains the T-cell receptor a chain, which plays an important role in the recognition of allergens. Significant linkage of IgE responses to several

allergens and total serum IgE has been found in certain T cell receptor a serotypes, suggesting that a gene in this region modifies specific IgE responses. An association between atopy and a gain-of-function polymorphism in the a subunit of the IL-4R on chromosome 16 has been found. There has also been evidence for linkage between 17p12-q11.2 regions and asthma, which contain genes coding for the C-C chemokines RANTES and eotaxin that play a critical role in eosinophil recruitment into asthmatic airways.

Another means in which genes may influence the course of allergic diseases such as asthma is by altering treatment responses to medications such as corticosteroids, $ß_2$ -adrenergic agents, and leukotriene modifiers. Some studies have found that the glutamate-27 $ß_2$ -adrenoceptor polymorphism is associated with less reactive airways in asthma. The glycine-16 form of the $ß_2$ -adrenergic receptor has been associated with a nocturnal fall in FEV_1 . A promoter polymorphism in the 5-lipoxygenase gene has been reported to alter transcription of this leukotriene-generating enzyme. Finally, an IL-4 promoter polymorphism associated with increased IL-4 gene transcription has been found to be associated with corticosteroid resistance and asthma severity, which is of interest because the combination of IL-2 and IL-4 has been found to induce corticosteroid resistance of T cells.

EPIDEMIOLOGIC TRENDS IN ATOPIC DISEASES

The worldwide prevalence of asthma, atopic dermatitis, and allergic rhinitis has been rising, particularly in Westernized metropolitan areas. Several epidemiologic studies suggest that changes in the infectious environment and in the pattern of microbial exposure of children associated with Westernization are important factors underlying the rising prevalence of atopic disorders over the past few decades in developed countries. Proponents of the “hygiene hypothesis” have suggested that the rise in allergy reflects deprivation of the developing immune system to microbial antigens that are needed for stimulation of Th1 cells.

In Western countries, life style has been associated with cleaner living conditions, fewer siblings, and widespread use of antibiotics for minor illnesses. Antibiotic use among young children may alter the microbial flora in the gastrointestinal tract and produce an environment that is less effective in driving a Th1 response. Consistent with this concept are recent studies demonstrating that 1 yr old infants in countries with a low prevalence of atopy have lactobacilli in their gastrointestinal tract whereas infants in countries with a high prevalence of atopy are colonized less often by lactobacilli and have a higher level of aerobic bacteria such as gram-negative bacilli and *Staphylococcus aureus*. This view is further supported by studies demonstrating that exposure of young children to other children at daycare centers protects against the development of asthma, presumably owing to an increased prevalence of viral infections, which are known to stimulate the Th1 response. These factors, combined with increased exposure to pollutants and indoor allergens, have been proposed to shift the immune system toward a Th2 phenotype and an increased prevalence of allergic disease. These new insights provide new opportunities for the development of novel immunomodulatory therapies directed at restoring the Th1/Th2 imbalance and reducing inflammation in asthma and other allergic diseases.

Chapter 131 - Diagnosis of Allergic Disease

Dan Atkins
Donald Y. M. Leung

Allergic diseases arise from the acute or chronic exposure of a sensitized individual to a specific allergen by inhalation, ingestion, contact, or injection. This results in symptoms that most often involve the nose, eyes, lungs, skin, or gastrointestinal tract either individually or in combination. A carefully obtained history, including environmental exposures, and the appropriate laboratory tests or allergen challenges is critical for an accurate diagnosis.

ALLERGY HISTORY

Obtaining a complete history from the allergic patient involves eliciting a description of all symptoms along with their timing and duration, exposure to common allergens, and responses to previous therapies. Because patients often suffer from more that one allergic disease, the presence or absence of other allergic diseases including allergic rhinitis, allergic conjunctivitis, asthma, urticaria, and atopic dermatitis should be determined. A family history of allergic disease is common because this is one of the most important factors predisposing a child to the development of allergies. Prospective studies suggest that the risk of allergic disease in a child approaches 50% when one parent is allergic and 66% when both parents are allergic.

Several characteristic behaviors are often seen in allergic children. Because of nasal pruritus and rhinorrhea, children with allergic rhinitis often perform the **allergic salute** by rubbing their nose upward with the palm of their hand. This maneuver gives rise to the **nasal crease**, a horizontal skinfold over the bridge of the nose. Characteristic vigorous grinding of the eyes with the thumb and side of the fist is frequently observed in children with allergic conjunctivitis. The **allergic cluck** is produced when the tongue is placed against the roof of the mouth to form a seal and withdrawn rapidly in an effort to scratch the palate. Importantly, the presence of other symptoms such as fever, unilateral nasal obstruction, and purulent nasal discharge suggests other diagnoses.

The timing of onset and the progression of symptoms are relevant. For example, the onset of recurrent or persistent nasal symptoms coinciding with placement in a daycare center might suggest recurrent infection rather than allergy. When patients present with a history of episodic acute symptoms it is important to review the setting in which symptoms occur as well as the activities and exposures that immediately precede their onset.

For example, in the patient whose symptoms are associated with lawn mowing, allergy to grass pollen or fungi is suggested, whereas if the symptoms always occur in homes with pets, then animal dander sensitivity is an obvious consideration. Reproducible reactions after the ingestion of a specific food raise the possibility of food allergy. When symptoms wax and wane but evolve gradually and are more chronic in duration, a closer look at whether the timing and progression of symptoms correlates with exposure to a seasonal aeroallergen is warranted.

Aeroallergens such as pollens or fungal spores are prominent causes of allergic disease whose concentration in outdoor air fluctuates seasonally. Correlating symptoms with the seasonal pollination patterns of indigenous plants along with information provided by local pollen counts can aid in identifying the allergen to which the patient is sensitized. Throughout most of the United States, trees pollinate in the early spring. Grasses pollinate in the late spring and early summer, whereas weeds pollinate in late summer through the fall. The presence of fungal spores in the atmosphere follows a seasonal pattern in the northern United States with spore counts increasing with the onset of warmer weather and peaking in the late summer months only to recede again with the onset of colder weather in the late fall through the winter. In warmer regions of the southern United States fungal spores and grass pollens may cause symptoms on a perennial basis.

Rather than experiencing seasonal symptoms, some patients suffer allergic symptoms year round. In these patients sensitization to sources of perennial allergens usually found indoors such as dust mites, animal dander, cockroaches, and fungi warrants consideration. Species of certain fungi such as *Aspergillus* and *Penicillium* are found indoors, whereas *Alternaria* is found in both indoor and outdoor environments. Cockroach allergens are often problematic in urban, inner city environments. Patients sensitive to perennial allergens often also become sensitized to seasonal allergens and experience baseline symptoms year round with worsening during the spring and fall pollen seasons.

The age of the patient is an important consideration in identifying potential allergens. Infants and young children are first sensitized to allergens that are in their environment on a continuous basis, such as dust mites, animal dander, and fungi. Clinically relevant sensitization to seasonal allergens usually takes several seasons of exposure to develop. Food allergies are more common in infants and young children, resulting primarily in cutaneous, gastrointestinal, and, less frequently, respiratory symptoms.

Complete information from all previous evaluations and prior treatments for allergic disease should be reviewed. A list of the medications used and the response to each should be determined. If allergen immunotherapy was previously administered, the duration of the treatment and its success or lack thereof should be noted. Improvement in symptoms during treatment with medications or therapies used to treat allergic disease provides additional evidence that the symptoms are the result

of an allergic process.

A thorough environmental survey should be performed with attention to potential sources of allergen and/or irritant exposure. The age and type of the dwelling, how it is heated and cooled, the use of humidifiers or air filtration units (either central or portable), and any history of flooding or water damage should be noted. Forced hot air heating may repeatedly stir up dust mite, fungi, and animal allergens. The irritant effects of wood burning stoves, fireplaces, and kerosene heaters may provoke respiratory symptoms in allergic patients. Increased humidity or water damage in the home is often associated with increased exposure to dust mites and fungi. Carpeting serves as a reservoir for dust mites, fungi, and animal dander. The number of domestic pets and their movements about the house, including where they sleep, should be ascertained. Special attention should be focused on the bedroom because children spend a significant portion of time there. The age and type of bedding, the number of stuffed animals, window treatments, and accessibility of the room to pets should be reviewed. The number of smokers in the home and where they smoke is useful information. Hobbies that might result in exposure to allergens or respiratory irritants such as paint fumes, cleansers, sawdust, or glues should be identified. Similar information should be obtained in regard to other environments where the child spends large portions of time such as a relative's home, the classroom, or daycare center.

PHYSICAL EXAMINATION

In patients with asthma, a peak flow analysis or spirometry should be performed and the results appraised for evidence of airways obstruction. If respiratory distress is observed, pulse oximetry should be performed. The child presenting with a chief complaint of rhinitis or rhinoconjunctivitis should be watched for mouth breathing, paroxysms of sneezing, sniffing, or rubbing of the nose and eyes. Infants taking a bottle or the breast should be observed for nasal obstruction severe enough to interfere with feeding as well as for evidence of aspiration or gastroesophageal reflux. A mental note should be made of the frequency and nature of coughing that occurs during the interview. A positional increase in coughing or wheezing should be noted. Children with asthma should be observed for congested cough, tachypnea at rest, retractions, or audible wheezes. Patients with atopic dermatitis should be monitored for repetitive scratching and the extent of skin involvement.

Because children with severe asthma as well as those receiving oral corticosteroids may suffer growth suppression, an accurate height should be plotted at regular intervals. Poor weight gain in a child with chronic chest symptoms should prompt consideration of cystic fibrosis. The blood pressure should be obtained to evaluate for steroid-induced hypertension. The patient with acute asthma may present with pulsus paradoxus, defined as a drop in systolic blood pressure during inspiration more than 10?mm?Hg. Moderate to severe airways obstruction is indicated by a decrease of more than 20?mm?Hg. An increased heart rate may be the result of an asthma flare or the use of a ß-agonist or decongestant. Fever is not caused by allergy alone and should prompt consideration of an infectious process.

Parents of allergic children are often concerned about a blue-gray to purple discoloration beneath the lower eyelids attributed to venous stasis and referred to as **allergic shiners**. They are found in up to 60% of allergic patients and almost 40% of patients without allergic disease. They are often accompanied by **Dennie lines** (Dennie-Morgan folds), which are prominent symmetric skinfolds that extend in an arc from the inner canthus beneath and parallel to the lower lid margin.

In most patients with allergic conjunctivitis, involvement of the eyes is usually bilateral. Examination of the conjunctiva reveals varying degrees of conjunctival injection and edema. In severe cases, periorbital edema may be observed involving primarily the lower eyelids. The classic discharge associated with allergic conjunctivitis is usually described as “stringy” or “ropy.” In children with vernal conjunctivitis, examination of the tarsal conjunctiva may reveal cobblestoning. Children repeatedly receiving large doses of oral corticosteroids for management of severe asthma are at risk for developing posterior subcapsular cataracts. Keratoconus, which is protrusion of the cornea, may occur in patients with atopic dermatitis as a result of repeated trauma produced by persistent rubbing of the eyes.

The external ear should be examined for eczematous changes in patients with atopic dermatitis. Because otitis media with effusion is common in children with allergic rhinitis, pneumatic otoscopic examination of the ear should be performed to evaluate for the presence of fluid in the middle ear and to exclude infection.

Examination of the nose in allergic patients often reveals the presence of a transverse nasal crease on top of the nose at the junction of the cartilaginous and bony portions of the nasal bridge caused by frequent rubbing of the nose. Nasal patency should be assessed and the nose examined for structural abnormalities affecting nasal airflow such as a septal deviation, turbinate hypertrophy, septal spurs, or nasal polyps. A decreased or absent sense of smell should raise concern about the presence of nasal polyps, a feature of cystic fibrosis. The nasal mucosa in allergic rhinitis is classically described as pale to purple in comparison to the beefy red mucosa of patients with nonallergic rhinitis. Allergic nasal secretions are typically thin and clear. Purulent secretions suggest another cause of rhinitis. The frontal and maxillary sinuses should be palpated to identify tenderness to pressure that might be associated with sinusitis.

Examination of the lips may reveal cheilitis caused by drying of the lips from continuous mouth breathing and repeated licking of the lips in an attempt to replenish moisture and relieve discomfort. Tonsillar and adenoidal hypertrophy along with a history of impressive snoring suggests the possibility of obstructive sleep apnea. The posterior pharynx should be examined for the presence of postnasal drip and posterior pharyngeal lymphoid hyperplasia.

Chest findings in asthmatic children vary significantly depending on disease duration, severity, and activity. In a child with mild or well-controlled asthma, the chest may appear entirely normal on examination between asthma exacerbations. However, examination of the same child during an acute episode of asthma may reveal tachypnea, cyanosis, use of accessory muscles, wheezing, and decreased air exchange with a prolonged expiratory time. Tachycardia may be caused by the asthma exacerbation or be accompanied by jitteriness and caused by treatment with β_2 -agonists. Decreased airflow or rhonchi and wheezes over the right chest may be noted in children with mucus plugging and right middle lobe atelectasis. Unilateral

wheezing after an episode of coughing and choking in a small child without a history of previous respiratory illness suggests aspiration of a foreign body. Wheezing limited to the larynx in association with inspiratory stridor is seen in older children and adolescents with vocal cord dysfunction. In children with chronic asthma an increased anteroposterior diameter of the chest suggests significant air trapping. In infants and younger children with significant asthma a groove along the lower ribs at the site of attachment of the diaphragm may be present. Digital clubbing is rarely seen in patients with uncomplicated asthma and should prompt further evaluation to rule out other potential diagnoses.

The skin of the allergic patient should be examined for evidence of urticaria/angioedema or atopic dermatitis. **Xerosis**, or dry skin, is the most common skin abnormality of allergic children. **Keratosis pilaris**, often found on the extensor surfaces of the upper arms and thighs, is characterized by roughness of the skin caused by keratin plugs lodged in the openings of hair follicles. Examination of the skin of the palms and feet reveals exaggerated palmar and plantar creases in some allergic children.

DIAGNOSTIC TESTING

The laboratory evaluation of the child suspected of having allergic disease should focus on obtaining objective evidence to support the diagnosis, documenting sensitivity to allergens implicated by the history, and ruling out other potential diagnoses.

In Vitro Tests.

Allergic diseases are often associated with increased numbers of eosinophils circulating in the peripheral blood and invading the tissues and secretions of target organs. Eosinophilia, generally defined as the presence of more than 450 eosinophils/µL of blood, is the most common abnormality noted on examination of the blood of allergic patients. Seasonal increases in the number of circulating eosinophils may be observed in sensitized patients after exposure to allergens such as tree, grass, and weed pollens. The number of circulating eosinophils can be suppressed by certain infections and the systemic administration of corticosteroids. In certain pathologic conditions such as drug reactions or eosinophilic pneumonias, significantly increased numbers of eosinophils may be present in the target organ in the absence of peripheral blood eosinophilia. Increased numbers of eosinophils are observed in a wide variety of disorders in addition to allergy (Box 131–1).

Nasal and bronchial secretions are often examined for the presence of eosinophils. The presence of eosinophils in the

sputum of asthmatic patients is a classic finding. Increased numbers of eosinophils in smears of nasal mucus stained with Hansel stain is a more sensitive indicator of nasal allergies than peripheral blood eosinophilia and aids in distinguishing allergic rhinitis from other causes of rhinitis. In young children, nasal eosinophilia is defined as the presence of more than 4% eosinophils in nasal mucus smears, whereas a finding of more than 10% eosinophils is required in adolescents and adults. Nasal mucus eosinophilia also has therapeutic implications, predicting a higher probability of responsiveness to topical nasal corticosteroid sprays.

An elevated IgE level is often found in the serum of allergic patients, because IgE is the primary antibody associated with allergic reactions. IgE levels are measured in

international units (IU), with 1?IU equal to 2.4?ng of IgE. Maternal IgE does not cross the placenta and, although the fetus is capable of producing IgE as early as the 11th week of gestation, infants in developed countries produce little IgE in utero owing to the lack of stimulation by allergens. Serum IgE levels gradually rise over the first years of life to peak in the teen years and decrease steadily thereafter. A variety of factors in addition to age, such as genetic influences, race, gender, certain diseases, and exposure to cigarette smoke and allergens, affect serum IgE levels. Serum IgE levels may increase 2- to 4-fold in allergic patients during and immediately after the pollen season, then gradually decline until the next pollen season. Comparison of total serum IgE levels among patients with allergic disease reveals that those with atopic dermatitis tend to have the highest levels, whereas patients with allergic asthma generally have higher levels than those with allergic rhinitis. Although average total serum IgE levels are higher in populations of allergic patients than in comparable populations without allergic disease, the overlap in levels is such that the diagnostic value of a total serum IgE level is poor. For example, approximately one half of patients with allergic disease have a total serum IgE level in the normal range. However, total serum IgE measurement is indicated when the diagnosis of allergic bronchopulmonary aspergillosis is suspected; total serum IgE concentration greater than 1,000?ng/mL is a criterion for diagnosis of this disorder. Continued monitoring of the total serum IgE in patients with allergic bronchopulmonary aspergillosis is encouraged because serum IgE levels decrease with appropriate therapy and rise again during exacerbations of the disease. The total serum IgE level is also elevated in several nonallergic diseases (Box 131–2).

The presence of IgE specific for a particular allergen can be documented in vivo by skin testing or in vitro by the measurement of allergen-specific IgE levels in the serum (Table 131–1). The most widely employed test for documenting the presence of allergen-specific IgE in the serum is the **radioallergosorbent test (RAST)**. In this test the allergens of an individual allergen extract are bound to a solid phase support. A small amount of the patient's serum is incubated with the allergen-coated support, and any IgE in the patient's serum specific for those allergens binds to them on the support. After rinsing, the allergen-coated support to which the patient's allergen-specific IgE is bound is incubated with radiolabeled antihuman-IgE, which then binds to the patient's allergen-specific IgE. Excess radiolabeled antihuman-IgE is rinsed away and the amount of radioactivity associated with the support to which allergen, the patient's allergen-specific IgE, and radiolabeled antihuman-IgE are attached is measured. Over the years improvements in the assay for allergen-specific IgE have included modification of the solid phase supports to enhance binding of allergen, substituting enzymes for the radiolabels on antihuman-IgE to increase the accuracy of detection while also providing a more stable reagent, and a switch to calibration curves based on known quantities of IgE resulting in quantitative rather than qualitative reporting of results.

The primary advantages of these assays in comparison to allergen skin testing are their safety and that the results are not influenced by skin disease or medications. Overall, the results of these tests correlate well with those obtained by skin testing and provocation challenges; however, the RAST is not as sensitive as the skin test. As a result, in patients with histories of life-threatening reactions to foods, insect stings, drugs, or latex, skin testing is still required because of its higher sensitivity even if the RAST is negative.

In Vivo Tests.

Allergen skin testing is the primary in vivo procedure for the diagnosis of allergic disease. Mast cells with allergen-specific IgE antibodies attached to high-affinity receptors on

† Because skin tests are more sensitive, they are more reliable than RAST in confirming life-threatening anaphylactic conditions if maximal sensitivity is required (e.g., penicillin, Hymenoptera hypersensitivity)

their surface reside in the skin of allergic patients. The introduction of minute amounts of an allergen to which the patient is allergic into the skin results in cross-linking by the allergen of allergen-specific IgE antibodies on the mast cell surface, thereby triggering mast cell activation. Once activated, these mast cells release a variety of preformed and newly generated mediators that act on surrounding tissues. Histamine is the mediator most responsible for the immediate wheal and flare reactions observed in skin testing. Examination of the site of a positive skin test reveals a pruritic wheal surrounded by an area of erythema. The time course of these reactions is rapid in onset, reaching a peak within approximately 20?min and usually resolving over the next 20–30?min. However, in some patients a larger area of less distinctly demarcated edema on an erythematous base develops at the skin test site over the next 6–12?hr. This reaction is referred to as a **late-phase response** and usually resolves by 24?hr. Biopsy of the site of a late-phase response reveals the presence of an inflammatory infiltrate consisting of T cells, neutrophils, and eosinophils. These reactions are thought to be similar to the late-phase responses observed in other organs such as the nose and lungs after provocation challenges.

Skin testing in children is usually first performed using the prick/puncture technique. With this technique a small drop of allergen is applied to the skin surface and a tiny amount is introduced into the epidermis by lightly pricking or puncturing the skin through the drop of extract with a small needle. When the prick/puncture skin test is negative and the history is suggestive, selective skin testing using the intradermal technique may be performed. This technique involves using a 26-gauge needle to inject 0.01–0.02?mL of a dilute allergen extract into the dermis of the arm. This technique is more sensitive than the prick/puncture technique and the allergen extracts used are 1,000- to 100-fold less concentrated than extracts used for prick/puncture testing. Intradermal skin tests are not recommended for use with food allergens because of the risk of triggering anaphylaxis. Irritant rather than allergic reactions can occur with intradermal skin testing if higher concentrations of extracts such as 1:100 weight/volume are used. Although less sensitive than intradermal skin tests, positive prick/puncture skin tests tend to correlate better with symptoms on natural exposure to the allergen.

Panels of skin tests are often applied that include the appropriate allergens for a given geographic area in addition to common indoor allergens; however, the number of skin tests performed should be individualized, taking into account the allergens suggested by the history. A positive and negative control skin test, using histamine and saline, respectively, is performed with each set of skin tests. A negative control is necessary to ensure that the patient is not dermatographic and that reactions caused merely by applying pressure to overly sensitive skin are not interpreted as due to allergen sensitivity. A positive control is necessary to establish the presence of a cutaneous response to histamine. Medications with antihistaminic properties in addition to adrenergic agents such as ephedrine and epinephrine have been demonstrated to suppress skin test responses and should be avoided for appropriate intervals before the placement of skin tests. Prolonged courses of systemic corticosteroids may suppress cutaneous reactivity by decreasing the number of tissue mast cells as well as their ability to release mediators.

Under certain circumstances, provocation testing is performed to examine the association between allergen exposure and the development of symptoms. Provocation challenges involving exposure of the skin, conjunctiva, nasal mucosa, oral mucosa, gastrointestinal tract, and lungs to allergens have been performed in a variety of clinical and research settings. Bronchial provocation challenges have been performed by having patients inhale increasingly concentrated solutions of nebulized allergen extracts and monitoring for airways obstruction by clinical observation and the performance of pulmonary function testing. In most studies the results of bronchial provocation challenges have correlated well with other clinical data obtained by skin testing and/or the performance of in vitro testing. Although a large number of bronchial provocation challenges to allergens have been performed safely, the possibility of a severe reaction and the time, expense, and expertise required for the performance of these tests limit their performance to a research setting.

Currently, the bronchial provocation test most frequently performed is to methacholine, which causes potent bronchoconstriction of asthmatic but not of normal airways. **Methacholine challenge testing** is performed to document the presence and degree of bronchial hyperreactivity in a patient suspected of having asthma. After baseline spirometry is obtained, increasing concentrations of nebulized methacholine are inhaled until a specified drop in lung function, such as a 20% decrease in FEV_1 , occurs or the patient is able to tolerate the inhalation of a set concentration of methacholine, such as 25?mg/mL, without a significant decrease in lung function.

Oral food challenges are performed to determine if a specific food causes symptoms or if a suspected food can be added to the diet. Food challenges are performed to those foods incriminated by the history and results of skin tests and/or in vitro testing. These challenges may be performed in an open, single-blind, double-blind, or double-blind placebo-controlled fashion and involve the ingestion of gradually increasing amounts of the suspected food at set time intervals until the patient either experiences a reaction or tolerates a normal portion of the food openly. Because of the potential for significant allergic reactions, these challenges should only be performed in an appropriately equipped facility with personnel experienced in the performance of food challenges and the treatment of anaphylaxis, including cardiopulmonary resuscitation.

Chapter 132 - Principles of Treatment of Allergic Disease

Dan Atkins
Donald Y. M. Leung

The basic principles of the treatment of allergic disease include the avoidance of exposure to allergens and irritants that trigger symptoms and the pharmacologic management of symptoms caused by inadvertent acute and chronic allergen exposures. In selected patients with allergic disease refractory to avoidance measures and optimal pharmacologic management, allergen immunotherapy may be considered.

ENVIRONMENTAL CONTROL MEASURES

Children spend the majority of their time in indoor environments, including their home, a school or daycare center, and the homes of friends and relatives. Over the years in an effort to save energy, houses and buildings have been built tighter and more insulated with fewer air exchanges over a given period. These changes have led to an increase in indoor humidity and higher concentrations of allergens and irritants in indoor air. Examination of indoor environments by epidemiologic studies in a variety of geographic areas suggests that house dust mite, cat, and cockroach allergens are the most common significant triggers of allergic disease in these settings, but exposures to allergens from other pets, pests, fungi, and respiratory irritants such as cigarette smoke can also be a problem.

Over 30,000 species of mites have been identified, but the term **dust mites** usually refers only to the pyroglyphid mites *Dermatophagoides pteronyssinus, Dermatophagoides farinae*, and *Euroglyphus maynei*, which are the major sources of allergen in house dust. Respiration and water vapor exchange occurs through the skin of dust mites, rendering them sensitive to decreases in humidity and temperature extremes. The regular use of humidifiers and swamp coolers has been shown to promote dust mite survival. Mites do not survive when the relative humidity drops below 50%. They feed on animal and human skin scales and other debris, which is why they exist in large numbers in mattresses and bedding as well as in carpet and upholstered furniture. They are also found in flour and mixes for baked

goods. Several reports have described anaphylaxis following the ingestion of baked goods such as waffles and pancakes prepared with flour infested with dust mites. Dust mite fecal pellets are a major source of allergens. They consist of partially digested food combined with digestive enzymes encased in a permeable membrane, which keeps the fecal pellets intact. These fecal pellets have been likened to pollen grains given their similarities in size (10–40?µm), the amount of allergen they contain, and their ability to rapidly release allergens on contact with moist mucous membranes. Mites can persist in imported furnishings for at least 2 yr, and mite allergens have been shown to remain stable under domestic conditions for periods of at least 4 yr. Most studies have suggested that minimal dust mite allergen becomes airborne during normal household activities and that a vigorous disturbance such as vacuuming without a vacuum bag or shaking a bed sheet is required to launch significant amounts of dust mite allergens into the air. Once airborne, dust mite allergen particles tend to settle out of the air relatively rapidly because of their size and weight. Nonetheless, dust mite allergen exposure likely occurs during sleep on mite-infested pillows and mattresses and during normal household activities when dust mite concentrations in the home are high enough. Studies examining concentrations of dust mite allergens in samples of settled house dust demonstrate that levels as low as 2?µg of dust mite allergen per gram of house dust can lead to sensitization, whereas levels of 10?µg per gram of house dust have been associated with the development of symptoms.

Appropriate environmental control measures can significantly reduce exposure to dust mite allergens. Major emphasis should be placed on reducing exposure to dust mite allergens in the bedroom and the bed because of the large amount of time children spend there. Encasements impermeable to dust mite allergens should be placed on all pillows, the mattress, and the box spring. Dust should be removed from the surface of these covers and the bed frame by vacuuming them weekly. The sheets and mattress pad should be washed weekly in hot water at a temperature hotter than 130°F. Minimizing the number of items in the room that collect dust such as books, drapes, toys, stuffed animals, and any clutter is recommended. Major reservoirs of dust mite allergen often more difficult to deal with include the carpet and upholstered furniture. These should be vacuumed weekly with an efficient double-bagged vacuum cleaner. Although the application of acaricides or denaturing agents to carpets and upholstered furniture has been advised, the actual benefit remains unclear and the amount of effort required may be more than most families are willing to invest. If possible, carpet removal, at least in the bedroom, may prove a better choice for eliminating a large reservoir of dust mite allergen. Other measures for dust mite allergen control include maintaining the indoor relative humidity less than 50% and keeping the air conditioning set at the lowest level during the warmer months.

In many countries more than half of the households have pets, the most common of which are cats and dogs. Cats are considered to be more sensitizing than dogs. With cats, dogs, horses, and cattle the major sources of allergens are hair, dander, and saliva, whereas the major source of rodent allergens is their urine. Studies of airborne cat allergen have shown that a significant portion is found on small particles that behave aerodynamically like spheres of less than 7?µm in diameter. As much as 30% of airborne cat allergen may reside on particles less than 5?µm. Particles this small may not be adequately filtered by the nose and could potentially be deposited in the airways. Their small size enables these particles to remain airborne for longer periods and to be suspended repeatedly by air currents from heating and ventilation systems or just by walking across the carpet or sitting in an upholstered chair. **Fel d 1,** the major cat allergen, is a highly charged protein that readily sticks to a variety of surfaces, including walls, carpeting, and upholstered furniture. Because of this adhesiveness cat allergens bind to their owner's clothing and are routinely transported to public buildings, including schools, where they have been measured in moderately high amounts. From these sites significant amounts of cat allergen can subsequently be carried into homes without cats. Analysis of house dust from homes with cats reveals levels of Fel d 1 ranging from 8?µg–1.5?mg/g of house dust. Levels of Fel d 1 in homes without cats vary from 0.2–80?µg/g of house dust. Sensitization to cat allergen has been associated with levels ranging from 1–8?µg/g of house dust. Carpets, upholstered furniture, and bedding serve as reservoirs of cat allergens, resulting in the persistence of significant amounts in the home for months after a cat has been removed. Complete avoidance of cat allergen is virtually impossible, although significant reduction in exposure to cat allergens is achievable.

Removing the pet from the home is obviously the most effective means of reducing exposure to animal allergens, although it has been demonstrated that without other interventions, such as removing carpeting and upholstered furniture and wiping down walls, it takes 6 mo or more for the levels of cat allergen to drop to a level found in houses without a cat. As a result, cat owners who remove their pets from their homes should be informed not to expect immediate results. Unfortunately, advice

to remove a pet from the home or keep it outdoors is often ignored. In contrast to dust mite allergens, cat allergen is light and remains suspended in the air for long periods of time. As a result, HEPA-filtered air cleaners are helpful in reducing the amount of airborne cat allergen. Other suggested methods include washing the cat regularly and maintaining a cat allergen free bedroom from which the cat is excluded and where mattress covers and air-filtering devices are used. The cat should also be restricted from other living areas where the sensitized child spends large amounts of time, such as the family room or other play areas. Regular vacuuming with a HEPA-filtered and double-thickness bag vacuum cleaner is also encouraged. Similar measures are suggested for the control of exposure to other animal allergens, although whether these measures reduce exposure to levels resulting in clinical improvement as demonstrated by decreased symptoms, improved peak flows, or decreases in bronchial hyperreactivity remains to be documented by appropriately controlled studies.

Infestation of the home by insects and other pests such as mice and rats is another potential source of significant allergen exposure in the indoor environment. Studies have identified the importance of exposure to cockroach allergens as a major risk factor for the development of asthma in inner-city children. Once sensitized, inner-city cockroach-sensitive asthmatic children with continued exposure to high levels of cockroach allergens in their bedrooms are at higher risk for urgent care visits and hospitalization than inner-city asthmatic children who are not allergic to cockroaches. Recommended methods to decrease cockroach allergen exposure include reducing access to the home by sealing cracks in the flooring and walls and removing sources of food and water by repairing leaky pipes, putting away food, and frequent cleaning. Regular extermination using baits or chemical treatment of

infested areas is also advised.

Efforts to improve indoor air quality should also encompass reducing exposure to respiratory irritants. Passive exposure to environmental tobacco smoke has been shown to worsen asthma and increase nasal symptoms in patients with allergic nasal disease. As a result, smoking cessation should be repeatedly encouraged and smoking indoors should never be permitted. The use of wood-burning stoves and fireplaces and kerosene heaters should be discouraged.

Although exposure to pollens and fungi primarily occurs outdoors, these allergens are detectable indoors during the warmer months when their levels indoors often reflect their prevalence in the outdoor environment. During the winter when the outdoor levels of other fungi are lowest, the indoor fungi *Aspergillus* and *Penicillium* are the most prevalent. Fungi are often found in damp basements and thrive in conditions associated with increased moisture in the home, such as water leaks, flooding, or increased humidity promoted by the excessive use of humidifiers or swamp coolers. As a result, exposure to indoor fungal allergens can be reduced by maintaining the indoor relative humidity less than 50%, removing contaminated carpets, and wiping down washable surfaces prone to fungal growth such as shower stalls, shower curtains, sinks, drip trays, and garbage pails with solutions of detergent and 5% bleach. Dehumidifiers should be placed in damp basements. Standing water at any site in the home should be eliminated and the cause addressed. Removing all items from the home that are prone to fungal contamination and growth is also encouraged. Keeping the windows and doors closed and using air conditioning to filter outdoor air can keep both indoor pollen and fungi levels to a minimum during the warmer months when outdoor levels of these allergens are at their peak. The use of window or attic fans is to be avoided. Laundry should be dried in a dryer rather than on a clothesline. Measures to avoid pollens and fungal spores when out of the house include closing the windows and using the air conditioner when traveling in the car, avoiding moldy vegetation, and wearing a mask when these materials cannot be avoided. Outdoor activities during periods of high pollen counts should be kept to a minimum. Someone other than the sensitized patient should mow the lawn and rake leaves. Frequent hand washing after outdoor play is suggested to avoid transferring pollens from the hands to the eyes and nose. At the end of the day, showering and shampooing is suggested to avoid contamination of the bed with allergens. During the day, the bed should remain covered with a bedspread.

PHARMACOLOGIC THERAPY

Adrenergic Agents.

Adrenergic agents exert their effects through the stimulation of cell surface a- and ß-adrenergic receptors in a variety of target tissues. These receptors belong to the G protein–coupled superfamily of receptors. In general, a-adrenergic receptor stimulation results in excitatory responses such as vasoconstriction, whereas ß-adrenergic stimulation leads to inhibitory responses such as bronchodilation. The a-adrenergic receptors have been classified into a_1 - and a_2 -adrenergic receptors. Further studies of these receptors in humans have identified three subtypes of a_1 -adrenergic receptors and three subtypes of a_2 -adrenergic receptors. The ß-adrenergic receptors are further divided into three subtypes: $ß_1$, $ß_2$, and $ß_3$. Each of these adrenergic receptors exhibits a distinctive tissue distribution. The physiologic response in a given tissue to the administration of an adrenergic agent depends on the specific receptor binding characteristics of the drug as well as the number and distribution of the various types of adrenergic receptors in the tissue. Epinephrine, the initial adrenergic drug used in Western medicine, remains the drug of choice for the treatment of anaphylaxis because of its combined a- and ß-adrenergic effects.

The a-adrenergic agents are effective in the treatment of allergic nasal disease because of their decongestant effects. In the nose, stimulation of a_1 -adrenergic receptors on postcapillary venules and a_2 -adrenergic receptors on precapillary arterioles leads to vasoconstriction, resulting in a reduction in nasal congestion. The oral decongestants used clinically include pseudoephedrine, phenylephrine, and phenylpropanolamine. They are available individually or in combination with antihistamines in liquid and tablet forms, including sustained-release preparations. Pseudoephedrine and phenylpropanolamine are rapidly and thoroughly absorbed, whereas phenylephrine, the less effective of the three drugs, is incompletely absorbed, resulting in a significantly lower bioavailability of approximately 38%. Peak plasma concentrations of these drugs are reached between 30?min and 2?hr of administration, but the decongestant effect has not been directly correlated to the plasma concentration. Pseudoephedrine and phenylpropanolamine are excreted essentially unchanged by the kidney. The use of oral decongestants should be avoided in patients with hypertension, coronary artery disease, glaucoma, or metabolic disorders such as diabetes or hyperthyroidism. Reported adverse effects of oral decongestants include excitability, headache, nervousness, palpitations, tachycardia, arrhythmias, hypertension, nausea, vomiting, and urinary retention. Decongestants available as topical nasal sprays include phenylephrine, oxymetazoline, naphthazoline, tetrahydrozoline, and xylometazoline. Given their efficacy and rapid onset of action, the potential for excessive use of topical nasal decongestants resulting in rebound nasal congestion is high. When this occurs, refraining from the use of these sprays for 2–3 days is necessary for recovery.

Drugs that stimulate ß-adrenergic receptors have been used for years in the treatment of asthma because of their potent bronchodilator effects. The subclassification of ß-adrenergic receptors into $ß_1$ and $ß_2$ subtypes led to the development of drugs selective for the $ß_2$ -adrenergic receptor that have the advantage of producing significant bronchodilation with less cardiac stimulation. In addition to their bronchodilating effects, $ß_2$ -adrenergic agonists have been reported to improve

mucociliary clearance, decrease microvascular permeability, inhibit cholinergic nerve transmission, and reduce mediator release in mast cells, basophils, and eosinophils. The ß-adrenergic agonists can be delivered orally, by inhalation, or by injection. The inhaled route is generally preferred because of the rapid onset of action and fewer adverse effects. Reported adverse effects of ß-adrenergics agents include tremor, palpitations, tachycardia, arrhythmias, central nervous system stimulation, hyperglycemia, hypokalemia, hypomagnesemia, and a transient increase in hypoxia, which is attributed to an increase in perfusion to inadequately ventilated areas of the

asthmatic lung.

Anticholinergic Agents.

These drugs inhibit vagally mediated reflexes by antagonizing the action of acetylcholine at muscarinic receptors. Of the available anticholinergic agents, ipratropium bromide is the most commonly used. It is a quaternary amine that is poorly absorbed across mucosal surfaces and does not readily cross the blood-brain barrier. As a bronchodilator, it has a slower onset of action than short-acting inhaled $ß_2$ -agonists and takes longer to reach maximal effect, which makes it less effective as a rescue medication. Ipratropium is available by prescription as a metered-dose inhaler delivering 18?µg/spray and as a 0.02% nebulized solution (500?µg/2.5?mL). Inhaled anticholinergics have very few adverse effects, although they occasionally trigger coughing.

Ipratropium given as a nasal spray (0.03–0.06%) has been shown to be effective in the reduction of rhinorrhea resulting from perennial nonallergic rhinitis, the common cold, or other triggers such as exposure to irritants or cold air. The use of ipratropium is limited in the treatment of moderate to severe allergic rhinitis because it does not alter other common allergic nasal symptoms, such as sneezing, nasal congestion, or pruritus. Nasal dryness and epistaxis are occasionally encountered with use of the nasal spray.

Antihistamines.

The release of histamine and its effects on surrounding tissues is central to the development of the symptoms classically associated with the allergic response. As a result, antihistamines are frequently used medications for the treatment of allergic disease. Histamine exerts its effects through binding with one of its three receptors, referred to as H_1 -, H_2 -, or H_3 -receptors. Histamine effects triggered through H_1 -receptor binding are those most relevant to allergic inflammation and include pain, pruritus, vasodilation, increased vascular permeability, smooth muscle contraction, mucus production, and the stimulation of parasympathetic nerve endings and reflexes. The human H_1 -receptor gene has been mapped to the distal short arm of chromosome 3. The antimuscarinic effect of some of the early H_1 -type antihistamines may be explained by the reported 45% homology of the H_1 -receptor with the human muscarinic receptor. The H_1 -type antihistamines prevent the effects of H_1 -receptor activation through reversible, competitive inhibition of histamine by binding to the H_1 -receptor. As a result, antihistamines work best in preventing rather than reversing the actions of histamine and are most effective when given at doses and dosing intervals resulting in the persistent saturation of target organ tissue histamine receptors.

The H_1 -type antihistamines are traditionally divided into six classes based on differences in their chemical structures (Table 132–1). These antihistamines are further divided into 1st-generation antihistamines, which, because of their lipophilicity, cross the blood-brain barrier to exert effects on the central nervous system, and 2nd-generation antihistamines, which exert minimal, if any, central nervous system effects because of their inability to cross the blood-brain barrier owing to their size, charge, and lipophobicity. The sedative effects and cognitive impairment associated with the use of 1st-generation antihistamines are well documented. Thus, one of the primary advantages of 2nd-generation antihistamines is that they are nonsedating or much less so than 1st-generation antihistamines.

TABLE 132-1 -- **Classification of Antihistamines (H1-antagonists)**

Class	Examples
Ethylenediamines	
First generation	Antazoline, pyrilamine, tripelennamine
Type II ethanolamines	
First generation	Carbinoxamine, clemastine, diphenhydramine
Type III alkylamines	
First generation	Brompheniramine, chlorpheniramine, triprolidine
Second generation	Acrivastine
Type IV piperazines	
First generation	Cyclizine, hydroxyzine, meclizine
Second generation	Cetirizine
Type V piperidines	
First generation	Azatadine, cyproheptadine
Second generation	Fexofenadine, loratadine
Type VI phenothiazines	
First generation	Methdilazine, promethazine

Both 1st- and 2nd-generation antihistamines are available in oral preparations. A number of 1st-generation antihistamines are available over the counter whereas other 1st-generation and all 2nd-generation antihistamines currently require a prescription. The only antihistamine available as an intranasal spray is azelastine. The benefit of this form of administration is the potential for a rapid onset of action within 15–30?min. Azelastine, which is systemically absorbed and can cross the blood-brain barrier, has been shown to cause central nervous system effects in some patients and is not currently approved for use in children younger than 12 yr of age.

Orally administered antihistamines are well absorbed, reaching peak serum concentrations within approximately 2?hr. High tissue concentrations of antihistamines are usually achieved, which likely accounts for the sustained suppression of wheal and flare reactions even after serum levels have significantly declined. Most antihistamines are metabolized by the hepatic cytochrome P450 enzyme system. As a result, elimination of antihistamines may be reduced in patients with hepatic impairment or by the simultaneous ingestion of inhibitors of this pathway, such as erythromycin and other macrolide antibiotics, ciprofloxacin, ketoconazole, itraconazole, and certain antidepressants such as nefazodone and fluvoxamine. Some antihistamines such as hydroxyzine and loratadine are converted to clinically active metabolites. Clearance of fexofenadine and cetirizine is reduced in

patients with impaired renal function. Cetirizine clearance is also reduced in patients with hepatic dysfunction.

The efficacy of antihistamines in the treatment of seasonal and perennial allergic rhinoconjunctivitis is well documented (see Chapter 133). When compared with other medications in regard to the relief of allergic nasal symptoms, antihistamines appear to be more effective than cromolyn sodium but significantly less effective than intranasal corticosteroids. Improvement in symptom relief in patients with allergic rhinitis has been reported when an antihistamine is given in combination with a decongestant or with an intranasal steroid. Numerous formulations combining antihistamines and decongestants are available. Antihistamines have also been shown beneficial in the treatment of acute and chronic urticaria/angioedema. With regard to asthma, a significant clinical effect of antihistamines at conventional doses is difficult to document other than the possible improvement offered by better control of allergic nasal symptoms.

The 2nd-generation antihistamines are often chosen for the treatment of allergic disease in children because of negligible sedative and anticholinergic effects in comparison to 1st-generation antihistamines without a sacrifice in efficacy. In addition, most 2nd-generation antihistamines are effective with once-daily dosing, which, because of the convenience, may improve adherence. However, the widespread availability of 1st-generation

antihistamines and their lower cost result in their continued use. The adverse effects most often encountered include the performance impairment and anticholinergic effects noted with the use of 1st-generation antihistamines. The anticholinergic adverse effects encountered may include drying of the mouth and eyes, urinary retention, constipation, excitation, nervousness, palpitations, and tachycardia. Prolongation of the QT interval and ventricular tachycardia (torsades de pointes) was reported in association with the use of two 2nd-generation antihistamines that have since been removed from the market; those currently in use have not been associated with concerning cardiac effects.

Chromones.

Cromolyn sodium, the disodium salt of 1,3-*bis* (2-carboxychromon-5-yloxy)-2-hydroxypropane, and nedocromil sodium, a pyranoquinoline dicarboxylic acid, are the two chromones used clinically for the treatment of allergic disorders. Neither cromolyn nor nedocromil is absorbed well orally, with only 1% of the swallowed dose being absorbed. Absorbed drug is not metabolized but is rapidly eliminated in approximately equal amounts by the kidneys and liver. These drugs must be applied topically to the mucosal surface of the target organ to be effective. Both drugs have been demonstrated to inhibit mast cell degranulation and mediator release. They are capable of suppressing the activation of a variety of cells such as eosinophils, neutrophils, macrophages, and epithelial cells and have been shown to inhibit the activity of afferent C-type sensory nerve fibers of the nonadrenergic noncholinergic nervous system. Both drugs inhibit the intracellular increase in free calcium after mast cell activation and have also been shown to phosphorylate a mast cell protein resembling moesin, which is thought to be involved in terminating mediator release. Despite these findings, the molecular mechanism of action of these drugs remains to be completely defined.

Cromolyn and nedocromil prevent both early- and late-phase allergic responses when administered before allergen exposure. They block allergen-induced increases in bronchial hyperresponsiveness as well as seasonal increases in nonspecific bronchial hyperresponsiveness. With prolonged use, both drugs are capable of reducing bronchial hyperresponsiveness. These drugs have no bronchodilator properties but are capable of inhibiting the bronchoconstrictive effects of a variety of stimuli, such as allergen challenge, exercise, hyperventilation with cold air, ultrasonically nebulized distilled water, and exposure to atmospheric and industrial pollutants.

Cromolyn and nedocromil are considered best used for the prophylactic treatment of mild allergic or extrinsic asthma but may also be of benefit in the treatment of nonallergic or intrinsic asthma. Because of their lack of bronchodilator properties, neither drug is useful for the treatment of acute asthma. When their effects are compared, nedocromil is the more potent of the two. Cromolyn is available for the treatment of asthma by prescription as a 1% solution (20?mg/2?mL) for nebulization or by metered-dose inhaler (800?µg/actuation). The suggested dose for the treatment of asthma is 20?mg of cromolyn two to four times/24?hr by nebulization or 1.6?mg two to four times/24?hr by metered-dose inhaler. In numerous studies, cromolyn has been demonstrated to be useful in the treatment of allergic rhinitis and allergic conjunctivitis. Preparations for the nasal and ocular administration of cromolyn are available without a prescription. The suggested dose for the treatment of allergic rhinitis is one spray in each nostril three to four times daily of a nasal spray containing 5.2?mg of cromolyn per spray. For the treatment of allergic conjunctivitis, the suggested dose is 1 drop in each eye four to six times a day of a 4% ophthalmic solution. Nedocromil is not available in a nebulized form but is available by metered-dose inhaler. The recommended dose for the treatment of asthma is 3.5?mg (1.75?mg/puff) two to four times/24?hr. A 2% solution of nedocromil is available by prescription for the treatment of allergic conjunctivitis at a suggested dose of 1–2 drops in each eye twice daily.

The safety of these drugs, even with prolonged administration, has been well documented. Dry throat and transient bronchoconstriction have been the most frequently reported adverse effects of cromolyn use for the treatment of asthma, with only rare reports of patients becoming sensitized to the drug. Some patients using nedocromil complain about its taste. Infrequently reported adverse effects of nedocromil include coughing, sore throat, rhinitis, headache, and nausea.

Glucocorticoids.

These are widely used in the treatment of allergic disorders because of their potent anti-inflammatory properties. The diverse anti-inflammatory actions of glucocorticoids are mediated by the regulation of expression of a variety of specific target genes. Glucocorticoids have been shown to inhibit the synthesis of numerous cytokines, including interleukin (IL)-1 through IL-6, tumor necrosis factor-a (TNF-a), and granulocyte-macrophage colony stimulating factor (GM-CSF). They also inhibit the synthesis of the chemokines IL-8, RANTES, eotaxin, macrophage inflammatory protein-1a (MIP-1a), and monocyte chemoattractant protein-1. The expression of

enzymes such as nitric oxide synthase, phospholipase A_2 , and the inducible form of cyclooxygenase in airway epithelial cells is altered by glucocorticoids. They also regulate the expression of intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1). The administration of glucocorticoids results in (1) alteration in leukocyte number and activity (redistribution, suppression of migration to sites of inflammation, decreased response to mitogens, and suppression of delayed hypersensitivity responses in the skin); (2) suppression of mediator release (decreased histamine synthesis and release, decreased synthesis of prostaglandins, and other products of arachidonic acid metabolism); (3) enhanced response to agents that increase cyclic adenosine monophosphate (prostaglandin E_2 and histamine via the H_2 receptor); and (4) enhanced response to ß-adrenergic agonists (increased synthesis of ß-adrenergic receptors and increased availability of epinephrine as a result of decreased extraneuronal uptake of catecholamines).

Glucocorticoids are administered topically in ophthalmic preparations, nasal sprays, creams and ointments, and metered-dose inhalers and as a solution for nebulization. Systemic administration is accomplished orally or parenterally. The proper use and efficacy of glucocorticoids in the treatment of allergic disease along with the adverse effects associated with their use are presented in later chapters in this section that include discussions of individual allergic diseases.

Leukotriene-Modifying Agents.

Drugs that alter the leukotriene pathway exert their clinical effects either by inhibiting leukotriene production or blocking receptor binding. These agents possess mild anti-inflammatory properties and exhibit bronchodilator effects. In addition to inhibiting the early and late-phase allergic response to inhaled allergen, they diminish bronchoconstriction induced by exercise and exposure to allergen, aspirin, and cold air. These agents are used in the treatment of asthma (see Chapter 134) and are under investigation for treatment of allergic rhinitis.

Theophylline.

Because of its bronchodilating effects, theophylline (1,3-dimethyxanthine) has been used for years for the treatment of acute and chronic asthma. Of the molecular mechanisms proposed to explain its mode of action, only nonspecific inhibition of phosphodiesterase isozymes and antagonism of adenosine receptors have been shown to occur at concentrations of the drug of clinical relevance. The bronchodilator effect of theophylline is likely caused by its action as a phosphodiesterase inhibitor, whereas its ability to antagonize adenosine receptors may play a role in other effects, such as the

attenuation of diaphragmatic muscle fatigue and diminishing adenosine-enhanced mast cell mediator release. Theophylline has been shown to inhibit the immediate- and late-phase pulmonary response to allergen challenge and to exhibit modest bronchoprotective effects. Selected anti-inflammatory and immunomodulatory effects of this drug have also been reported. Theophylline is available by prescription as both rapidly absorbed and slow-release formulations. It is often administered intravenously when used for the treatment of severe acute asthma. The therapeutic and toxic effects of theophylline are related to the serum concentration, with the incidence of toxic effects significantly increasing as the serum levels approach and exceed 20?µg/mL. A variety of conditions and medications are capable of increasing or decreasing theophylline metabolism. The toxic effects of theophylline range from mild nausea, insomnia, irritability, tremors, and headache to cardiac arrhythmias, seizures, and death. As a result, the routine monitoring of theophylline levels is indicated. Because of the introduction of other effective therapies for the treatment of acute and chronic asthma, the need to monitor theophylline levels routinely and the potential for significant toxicity, the role of theophylline in the treatment of asthma has contracted significantly in recent years (see Chapter 134).

Lodoxamide Tromethamine.

This mast cell stabilizer is more effective than topical cromolyn sodium in alleviating signs and symptoms of allergic ocular disease (see Chapter 141). It is used in children older than age 2 yr for vernal keratoconjunctivitis, vernal conjunctivitis, and vernal keratitis. Occasional adverse effects have included transient burning or stinging after instillation.

Olopatadine Hydrocholoride.

This is both a mast cell stabilizer and an H_1 -receptor antagonist effective in relieving signs and symptoms of allergic conjunctivitis after topical instillation. It is labeled for use in children at least 3 yr of age. Headaches have occurred in 7% of patients treated; burning and stinging have occurred in fewer than 5%.

New and Future Therapies.

An increased understanding of the allergic inflammatory cascade has led to the development and investigation of a variety of new potential therapeutic agents for the treatment of allergic disease. Monoclonal anti-IgE antibodies (anti-IgE) have been developed that bind to circulating IgE at a site that prevents its subsequent attachment to the high affinity receptors for IgE on the mast cell surface. The parenteral administration of anti-IgE has been shown to reduce free serum IgE concentrations, inhibit skin test responses in allergic patients, suppress early- and late-phase responses to allergen, and decrease sputum eosinophilia in asthmatics. Clinical trials have demonstrated a beneficial effect of anti-IgE in the treatment of patients with allergic rhinitis and asthma. Serious adverse effects have not been encountered with this therapy. Anti-IgE may also be of benefit in the treatment of other allergic disorders such as anaphylaxis, atopic dermatitis, and food allergy. The cost of anti-IgE therapy requires careful patient selection with special consideration for those patients with persistent symptoms despite aggressive pharmacotherapy, those suffering from significant adverse effects of their current therapy, and patients with more than one allergic disorder.

Several strategies for inhibiting the actions of proinflammatory cytokines are under investigation. Approaches include the use of recombinant soluble receptors that attach to a specific cytokine and inhibit subsequent binding to cell surface receptors, the development of specific cytokine receptor antagonists and the administration of

humanized monoclonal anticytokine antibodies. Recombinant soluble IL-4 receptor antagonists exert their effects by binding to and inactivating IL-4 before it can attach to its cell surface receptor. Initial studies of inhaled soluble IL-4 receptor in patients with moderate asthma requiring inhaled corticosteroids suggested a beneficial clinical effect, but further investigation is indicated. Humanized monoclonal anti-IL4 antibodies are in development. A soluble receptor antagonist for IL-13, a cytokine with similarities to IL-4, is being developed. Clinical trials of humanized monoclonal anti-IL-5 antibodies administered by injection to asthmatic patients revealed a decrease in circulating eosinophils and sputum eosinophilia, but this effect was unaccompanied by a reduction in methacholine reactivity or a suppression of the early- or late-phase response to allergen.

The use of cytokines with anti-inflammatory effects in the treatment of allergic disorders is under investigation. Unfortunately, initial studies have not demonstrated a beneficial effect of IL-10 or interferons in the treatment of asthma. Although studies have documented that IL-12 administration is associated with a decrease in eosinophil accumulation in response to allergen challenge, inhibition of early- and late-phase responses to allergen or decreases in bronchial hyperreactivity have not been observed. In addition, the high incidence of significant adverse effects encountered with IL-12 administration limits its potential as a viable therapeutic option.

Other therapies under consideration for the treatment of allergic disease include the development of agents to inhibit the actions of chemokines, adhesion receptors, phosphodiesterase-4, and tryptase. Refinement of these potential therapies and continued research examining the molecular and cellular interactions of the allergic inflammatory cascade promises a host of new therapeutic approaches to the treatment and possible cure of allergic disease.

ALLERGEN IMMUNOTHERAPY

Allergen immunotherapy is the process of administering gradually increasing doses of allergens to a person with allergic disease for the purpose of reducing or eliminating the patient's adverse clinical response on subsequent natural exposure to those allergens. When properly administered to an appropriate candidate, allergen immunotherapy is a safe, effective form of therapy capable not only of reducing or preventing symptoms, but of potentially altering the natural history of the disease by minimizing disease duration and preventing disease progression.

Mechanisms.

A number of alterations in the immune response to allergen after allergen immunotherapy have been identified. Reciprocal changes in the levels of circulating allergen-specific IgE and IgG have been documented. After an early increase triggered by the onset of allergen administration, serum allergen-specific IgE levels gradually fall below initial levels over the course of treatment. The usual postseasonal rise observed in allergen-specific IgE levels is also blunted. However, clinical improvement often does not correlate well with allergen-specific IgE levels because a reduction in symptoms may occur even while allergen-specific IgE levels are increased or before their decline. In contrast to the reduction in allergen-specific IgE levels, the production of allergen-specific IgG is stimulated by allergen immunotherapy. These allergen-specific IgG antibodies have been called blocking antibodies because their interaction with allergen inhibits its subsequent binding to allergen-specific IgE. In Hymenoptera venom–sensitive patients a rise in venom-specific IgG antibody levels has been shown to correlate with protection over the first few years of treatment. Most studies involving other allergens have demonstrated an association between increasing allergen-specific IgG levels and decreasing symptom-medication scores, although some studies report patients with reduced symptoms in the absence of an allergen-specific IgG response, whereas others describe patients without improvement despite high levels of allergen-specific IgG. Thus, blunting of the allergen-specific IgE response and stimulation of allergen-specific IgG production are not the sole mechanisms responsible

for the clinical improvement associated with allergen immunotherapy but represent markers of modulation of the immune response to allergen.

Allergen immunotherapy also leads to changes in cellular elements of the immune response. Not only is the number of mast cells and basophils in target tissues reduced by allergen immunotherapy, but mediator release by these cells after allergen exposure is also diminished. The decline in mast cell and basophil numbers in target tissue combined with a reduction in mediator release by these cells results in decreased numbers of infiltrating inflammatory cells and subsequent suppression of the late-phase allergic response. Regulatory T-cell function is modulated by allergen immunotherapy, as evidenced by documented increases in T-lymphocyte suppressor activity. T-cell cytokine production is shifted with decreases in IL-4 production and increases in the production of interferon-?, IL-2, and IL-12. In addition, there is a decrease in the production of histamine-releasing factors by a host of other cells, including lymphocytes, alveolar macrophages, platelets, and vascular endothelial cells.

Indications and Contraindications.

Allergen immunotherapy is reserved for patients with an allergic disease that has been demonstrated to respond to this form of therapy such as seasonal or perennial allergic rhinoconjunctivitis, asthma triggered by allergen exposures, and insect venom sensitivity. Proof of the efficacy of allergen immunotherapy for the treatment of atopic dermatitis, food allergy, latex allergy, or acute or chronic urticaria is lacking, and therefore allergen immunotherapy is not recommended for the treatment of these disorders. Before considering allergen immunotherapy, sensitivity of the patient to the allergens to be administered should be documented by a positive skin test or an in vitro test revealing an increased serum level of allergen-specific IgE. In addition, the clinical relevance of these allergens should be supported by a history of symptoms on known exposure or a timing of symptoms that correlates well with suspected allergen exposure such as the presence of allergic nasal and ocular symptoms throughout the late summer and fall in a child with a large positive ragweed skin test. The duration and severity of the patient's symptoms should warrant the expense, effort, and risk associated with the administration of allergen immunotherapy. The presence of disabling symptoms in spite of a trial of allergen avoidance and appropriate medications at a suitable dose should be documented. For patients sensitized to seasonal allergens, more than two consecutive seasons of

symptoms are usually required before allergen immunotherapy is recommended unless the symptoms are unusually severe or the adverse effects of medication are unacceptable. The obvious exception to this rule is the child with insect sting anaphylaxis who should be started on venom immunotherapy once the sensitivity is correctly diagnosed.

Other factors that may affect the decision to institute allergen immunotherapy include quality of life issues such as the amount of school missed or medical resource utilization, the age of the patient, and other logistical factors. With the exception of venom immunotherapy, few data for the efficacy of allergen immunotherapy in children younger than 5 yr of age are available. Allergen immunotherapy is currently not recommended for children younger than 5 yr because of their increased risk of systemic reactions, the special expertise required to treat anaphylaxis in this age group, their potential inability to communicate clearly with their physician in the event of an allergic reaction, and their age-related potential for emotional distress with frequent injections. Other important logistic factors include the willingness of the patient to comply with a schedule of frequent injections over the course of several years, cost considerations, and the availability of an appropriate setting for the administering allergen immunotherapy.

Allergen immunotherapy is contraindicated in children on ß-blocker therapy as well as those with certain immunologic or autoimmune disorders, allergic bronchopulmonary aspergillosis, hypersensitivity pneumonitis, severe psychiatric disturbance, or a medical condition that would impair the ability to survive an allergic reaction. Pregnancy is a contraindication for the initiation of allergen immunotherapy or dosing increases, although pregnant adolescents can continue to receive their usual maintenance dose. Patients with unstable asthma should not be placed on allergen immunotherapy because of their increased risk for fatal anaphylaxis. Allergen immunotherapy is not used for the treatment of allergic bronchopulmonary aspergillosis or hypersensitivity pneumonitis because it has never been proven to be of benefit. Children on ß-blockers should be switched to another form of therapy before allergen immunotherapy is considered because of an increased intensity of allergic reactions and a poor response to conventional therapy. Allergen immunotherapy is usually avoided for patients with autoimmune disorders because of the potential for unanticipated stimulation of the immune system, resulting in disease activation.

Allergen Extracts.

The potency of the aqueous extracts used in allergen immunotherapy is affected by numerous factors. Allergens from weed and grass pollens are more easily extracted in aqueous solutions and, as a result, are generally more potent than extracts obtained from other sources, such as molds, tree pollens, and dust mites. Allergen extracts from fungal allergens because of their complexity are more variable than extracts of pollen allergens. Refrigeration and appropriate handling of allergen extracts used in allergen immunotherapy are important because degradation of many allergen extracts, such as those from tree, grass, and weed pollens and dust mites, may occur at higher temperatures. Dilute extracts are more susceptible to loss of potency resulting from adherence of allergen to the glass vial than are more concentrated extracts. To combat this effect, human serum albumin is sometimes added to dilute allergen extracts. Some allergen extracts, such as those from cockroaches, dust mites, and fungi, contain proteases capable of degrading other allergens in the extract. As a result it is often recommended that these allergens not be mixed with those from tree, grass, and weed pollens. Insect venoms are never mixed with other allergens. When available, the use of standardized allergen extracts is preferred to ensure consistency in dosing and avoid the variability in allergen content encountered with allergen extracts that are not standardized.

Allergen Extract Administration.

The goal of allergen immunotherapy is to gradually increase the dose of allergen extract administered until the injection of an “optimal” maintenance dose containing 4–12?µg of each major allergen in the extract is reached. The mixture of allergen extracts administered during the course of allergen immunotherapy is individually formulated for each patient based on their documented sensitivities. Although various dosing schedules are used, initial injections are most often given at 5–10 day intervals year round. Schedules of allergen administration are selected based on the sensitivity of the patient to the allergens in the extract. The most sensitive patients are advanced to maintenance dose more gradually. Doses of allergen immunotherapy are increased according to a set schedule while taking into account the reaction to the previous injection. Usually 5–6 mo of weekly injections are required to reach the maintenance dose, although it may take longer in patients with marked sensitivity whose dosing schedule must be adjusted because of reactions to the injections. Unique schedules for the administration of insect venoms are used that differ from those for the administration of other allergens. Once the maintenance dose is reached and well tolerated, the time interval between injections is increased to

every few weeks to once a month. Because allergen extracts gradually lose potency, the first dose from a fresh replacement vial of maintenance allergen extract is reduced from 25–75% and increased in increments weekly until the usual maintenance dose is reached. The recommended length of a course of allergen immunotherapy is 3–5 yr. Insect venom immunotherapy may be continued longer in patients with histories of life-threatening anaphylaxis. Patients who have not improved after 1 yr of receiving maintenance doses of an appropriate allergen extract are unlikely to benefit and should have their allergen immunotherapy discontinued. Most patients enjoy a sustained improvement after allergen immunotherapy whereas others experience a gradual return of symptoms. Those who experience a relapse may respond to another course of treatment.

Rush immunotherapy involves the administration of multiple injections either in a single day or over several days in an attempt to reach maintenance dose more rapidly. The risk of adverse reactions, including systemic reactions, is higher than that encountered with traditional allergen immunotherapy schedules; and, as a result, these patients are often pretreated with antihistamines and corticosteroids. Because children are at even greater risk for adverse reactions with rush immunotherapy, carefully weighing the benefits versus the risks is warranted before using it.

Although allergen immunotherapy is regarded as safe, the potential for anaphylaxis always exists when patients are injected with extracts containing allergens to which

they are sensitized. As a result, allergen immunotherapy should only be offered in medical settings where a physician with access to emergency equipment and medications required for the treatment of anaphylaxis is available. Allergy shots should never be given at home or by untrained personnel. Patients should remain in the office for 20–30?min after the injection because most reactions to allergen immunotherapy begin within this time frame. Fatal anaphylaxis triggered by allergen immunotherapy, although rare, is estimated to occur at an incidence of 1 per 2 million injections. The risk of an adverse reaction is increased by dosage errors and the use of rush immunotherapy schedules. Particular caution is warranted when injections from a new vial are given. Patients with exquisite sensitivity, unstable asthma, or those experiencing exacerbations of allergic rhinitis or asthma are also at increased risk for adverse reactions. Giving allergen immunotherapy to patients on ß-blockers is contraindicated. Precautions to reduce significant adverse reactions include using standardized extracts, allowing only trained personnel to administer injections, paying careful attention to detail when giving injections, ensuring that the patient is medically stable beforehand, having appropriate medications and equipment available, and requiring the patient to remain in the office for 20–30?min after each injection. In some asthmatic patients, checking peak flows or spirometry before receiving an injection is also advisable.

Other forms of allergen immunotherapy have been proposed, including local nasal immunotherapy, oral aeroallergen immunotherapy, and the use of alum-precipitated allergen extracts. Local nasal immunotherapy is administered by having the patient spray allergen solutions into the nose at scheduled intervals. Although some studies show encouraging results, adequate long-term data are not available to currently support the routine use of this form of therapy. Although selected studies of oral and sublingual aeroallergen administration have reported favorable results, further studies demonstrating efficacy are required. A desire to decrease the likelihood of allergic reactions induced by the administration of aqueous allergens led to the development of alum-precipitated extracts in which the proteins are precipitated with aluminum hydroxide and alum-precipitated pyridine-extracted extracts. Because of the small number of available extracts and the inability to mix them with other aqueous extracts, their use remains limited. Another method developed to reduce allergenicity while maintaining immunogenicity is the polymerization of allergen extracts with glutaraldehyde. When these extracts are used the maintenance dose can be reached within 2 mo with a markedly reduced incidence of systemic reactions. These extracts have not yet been approved for use in the United States.

Efficacy.

The majority of well-designed clinical trials examining the impact of allergen immunotherapy on seasonal or perennial allergic rhinitis or rhinoconjunctivitis recommend it as an effective mode of therapy. In regard to the treatment of allergic rhinitis, birch, mountain cedar, grass, ragweed, and *Cladosporium* are allergens for which the efficacy of allergen immunotherapy has been best documented. Studies examining allergen immunotherapy with other allergens commonly used for the treatment of allergic rhinitis are either lacking or inconclusive. As with allergic rhinitis, most of the controlled trials examining the effects of allergen immunotherapy on seasonal or perennial allergic asthma also report favorable results. A meta-analysis of 20 trials examining the effects of allergen immunotherapy on allergic asthma revealed a significant increase in the odds for improvement after treatment along with fewer symptoms, improved pulmonary functions, less need for medication, and a reduction in bronchial hyperreactivity. The most convincing data for the benefit of allergen immunotherapy in the treatment of allergic asthma are available for birch, mountain cedar, grass, ragweed, and dust mite, with less conclusive, but suggestive data available for *Cladosporium*, *Alternaria*, and cat allergens. As would be expected, studies examining the effects of allergen immunotherapy in the treatment of patients with allergic rhinitis and allergic asthma have usually documented increases in circulating allergen-specific IgG and decreases in allergen-specific IgE after treatment. Reductions in sensitivity to administered allergens have been demonstrated in nasal and bronchial challenges. In addition, these studies have often shown that the late-phase response after allergen challenge is ablated or significantly reduced. The protective benefit as well as the safety of venom immunotherapy in patients with sensitivity to Hymenoptera venoms has also been well documented in several large studies. The efficacy of allergen immunotherapy for the treatment of food allergy, atopic dermatitis, urticaria, and latex allergy has not been documented.

Chapter 133 - Allergic Rhinitis

Henry Milgrom
Donald Y. M. Leung

In affluent societies 20–40% of children suffer from allergic rhinitis (AR). Over the past 40 yr there has been a substantial rise in AR in industrialized regions and a smaller increase in undeveloped countries and rural populations. The diagnosis is generally established by 6 yr of age and may be made in infants. The prevalence peaks late in childhood. Risk factors include family history of atopy, serum IgE greater than 100?IU/mL before age 6 yr, and higher socioeconomic group. The risk is increased in children introduced to foods or formula early in infancy, whose mothers smoke heavily especially before the child is 1 yr old, and with heavy exposure to indoor allergens.

Etiology.

Two factors required for manifestation of AR are sensitivity to an allergen and its presence in the environment. AR may be seasonal or perennial. Inhalant allergens are the main reason for both. **Seasonal allergic rhinitis** (SAR) follows a well-defined course of cyclical exacerbation, whereas **perennial allergic rhinitis** (PAR) causes year-round symptoms. Approximately 20% of cases are strictly seasonal, 40% perennial, and 40% mixed (perennial with seasonal exacerbations). In temperate climates, airborne pollen responsible for SAR appear in distinct phases: trees pollinate in the spring, grasses in the early summer, and weeds in the late summer. Mold spores are also important aeroallergens that tend to settle in the lower airways. In temperate climates the spores persist outdoors only in the summer, but in warm climates they occur throughout the year. Symptoms of seasonal allergies cease with the appearance of frost. Knowledge of the occurrence of seasonal symptoms, of the regional patterns of pollination and mold sporulation, and of the patient's specific IgE is necessary to establish the cause of SAR. PAR is most often associated with indoor allergens: house dust mites, animal danders, and molds. Cat and dog allergies are of major importance in the United States. The allergens from the saliva and sebaceous secretions can remain airborne for prolonged time. The ubiquitous major cat allergen, Fel d 1, may be found in such “cat-free” settings as

schools and hospitals because individuals can carry the allergen in on their clothing.

Pathogenesis.

The exposure to an allergen in an atopic host leads to IgE production and the infiltration of the nasal mucosa by inflammatory cells. The clinical reactions on re-exposure to the allergen have been designated as **early-phase responses** and **late-phase allergic responses**. Bridging of the IgE molecules on the surface of mast cells by allergen initiates the early responses, which are characterized by degranulation of mast cells and the release of preformed and newly generated inflammatory mediators, including histamine, prostaglandin E_2 , and the cysteinyl leukotrienes. The targets of inflammation in the nasal mucosa are the mucus glands, nerves, blood vessels, and venous sinuses.

Late-phase responses arise 4–8?hr after allergen exposure and are accompanied by the infiltration of cytokine-secreting T cells and eosinophils with secretion of eosinophil-derived mediators—major basic protein, eosinophil cationic protein, and leukotrienes—which cause damage to the epithelium, leading to the clinical and histologic appearance of chronic allergic disease. Repeated intranasal introduction of allergens causes “priming,” a brisk response to a reduced provocation dose.

Clinical Manifestations.

Symptoms of AR are often ignored or mistakenly attributed to a respiratory infection. Although older children blow their noses, younger ones tend to sniff and snort. Nasal itching brings on grimacing, twitching, and picking of the nose, which may result in epistaxis. Children with AR often perform the **allergic salute,** an upward rubbing of the nose with an open palm or extended fingers. This maneuver gives rise to the **nasal crease,** a horizontal skinfold over the bridge of the nose.

Typical complaints include intermittent nasal congestion, itching, sneezing, clear rhinorrhea, and conjunctival irritation. Symptoms increase with greater exposure to the responsible allergen. The patients may lose their sense of smell and taste. Some experience headaches, wheezing, and coughing. Nasal congestion is often more severe at night, causing mouth breathing and snoring, interfering with sleep and inducing irritability.

Diagnosis.

Evaluation of AR should include a patient history, physical examination, and laboratory evaluation. The diagnosis of AR is based on symptoms in absence of an upper respiratory tract infection or structural abnormalities. AR is characterized by symptoms that include sneezing, rhinorrhea, nasal itching, and congestion; and the laboratory findings of elevated IgE, specific IgE antibodies, and positive allergy skin tests. SAR differs from PAR by history and skin test results. Nonallergic rhinitides cause sporadic symptoms and may resemble PAR. Their causes are often unknown. Nonallergic inflammatory rhinitis with eosinophils (NARES) imitates AR in presentation and response to treatment, but the patients do not have elevated IgE antibodies. Vasomotor rhinitis is characterized by excessive responsiveness of the nasal mucosa to physical stimuli. Other nonallergic conditions such as infectious rhinitis, structural problems including nasal polyps and septal deviation, rhinitis medicamentosa (due to the overuse of topical vasoconstrictors), hormonal rhinitis associated with pregnancy or hypothyroidism, neoplasms, vasculitides, and granulomatous disorders may mimic AR.

PHYSICAL EXAMINATION.

Signs on physical examination include abnormalities of facial development, dental malocclusion, the **allergic gape** (continuous open-mouth breathing), **allergic shiners** (dark circles under the eyes), and the transverse nasal crease. Conjunctival edema, itching, tearing, and hyperemia are frequent findings. A nasal examination performed with a source of light and a speculum may reveal clear nasal secretions; edematous, boggy, and bluish mucous membranes with little or no erythema; and swollen turbinates that may block the nasal airway. Thick, purulent nasal secretions indicate the presence of infection. Children with AR often have related sinusitis, otitis media, serous otitis, eczema, or asthma.

Laboratory Findings.

Epicutaneous skin tests are the best method for detection of allergen-specific IgE. They are inexpensive and sensitive, and the risks and discomfort are minimal. Children younger than 1 yr often do not display any positive reactions to seasonal allergens. Positive skin tests to seasonal respiratory allergens are rare before two seasons of exposure. To avoid false-negative results, montelukast should be withheld for 1 day, most sedating antihistamine preparations for 3–4 days, and nonsedating antihistamines for 5–7 days. Serum immunoassays for IgE to allergens provide a suitable alternative for patients with dermatographism or extensive dermatitis, those taking medications that interfere with mast cell degranulation, those at high risk for anaphylaxis, and those who cannot cooperate with the procedure. Eosinophils in the nasal smear support the diagnosis of AR and neutrophils of infectious rhinitis. Blood eosinophilia and total serum IgE concentrations have relatively low sensitivity.

Treatment.

Safe and effective prevention or relief of symptoms is the goal of treatment. The removal or avoidance of offending allergens is advised (see Chapter 132). Sealing the mattress, pillow, and covers in allergen-proof encasings is the most effective strategy for the reduction of mite allergen. Bed linen and blankets should be washed every week in hot water (>130°F).

The only effective measure for evading animal allergens in the home is the removal of the pet. Avoidance of pollen and outdoor molds can be accomplished by staying in a controlled environment. Air conditioning allows for keeping windows and doors closed to lower the pollen exposure. HEPA filters reduce the counts of airborne mold spores.

Oral antihistamines administered as needed are suitable pharmacotherapy for the patient with mild, intermittent symptoms. Antihistamines relieve sneezing and rhinorrhea. The 2nd-generation antihistamines are preferred because they cause less sedation. Four are currently available: cetirizine (2–5 yr: 2.5?mg PO once daily; =6 yr: 5–10?mg PO once daily), loratadine (2–5 yr: 5?mg PO once daily; =6 yr: 10?mg PO once daily), fexofenadine (6–11 yr: 30?mg PO bid; =12 yr: 60?mg PO bid or 180?mg PO qd), and azelastine nasal spray (5–11 yr: 1 spray/nostril bid; =12 yr: 2 sprays/nostril bid). Pseudoephedrine (available without prescription; 2–6 yr: 15?mg PO q6h; 6–12 yr: 30?mg PO q6h; >12 yr: 60?mg PO q6h), an oral vasoconstrictor that can be associated with irritability and insomnia, may be used for nasal congestion, and the anticholinergic nasal spray ipratropium bromide (2 sprays/ nostril bid or tid, use 0.03% preparation) can be used for serous rhinorrhea. Intranasal decongestants may be used for less than 5 days, not to be repeated more than once a month. Sodium cromoglycate (available without prescription) is effective but requires frequent administration (every 4?hr). Leukotriene-modifying agents have a modest effect on rhinorrhea and nasal blockage.

Patients with more persistent, severe symptoms require treatment with intranasal corticosteroids. These agents are effective for all symptoms of AR with eosinophilic inflammation but not for rhinitis associated with neutrophils or free of inflammation. The older drugs beclomethasone, triamcinolone, and flunisolide are absorbed from the gastrointestinal tract as well as from the respiratory tract. Fluticasone (>4 yr: 1–2 sprays/nostril once daily), mometasone (3–11 yr: 1 spray per nostril once daily; >11 yr: 2 sprays/nostril once daily), and budesonide (>6 yr: 1–2 sprays/nostril once daily) have lower bioavailability and a better safety profile.

A consultation with an allergist is recommended for patients with AR who do not respond to treatment. The allergist may propose more effective avoidance measures and/or immunotherapy. Allergen immunotherapy interferes with IgE production and allergen-induced allergic symptoms and has been found to be effective in the treatment of AR.

Complications.

Chronic sinusitis is a frequent complication of AR, most often associated with purulent infection, but a proportion of patients develop marked mucosal thickening, sinus opacification, and nasal polyposis with inflammation but negative cultures. The inflammatory process is characterized by marked eosinophilia. Allergens may be the inciting agents. The sinusitis of **triad asthma** (asthma, sinusitis with nasal polyposis, and aspirin sensitivity) often shows poor response to therapy. Patients who undergo repeated endoscopic surgery derive diminishing benefit with each successive procedure.

Approximately 60% of patients with AR have asthma and even those who do not may manifest bronchial hyperresponsiveness. In patients who have both disorders, the aggravation of AR coincides with exacerbation of asthma and the treatment of nasal inflammation often reduces bronchospasm. Postnasal drip associated with AR commonly causes persistent or recurrent cough. Eustachian tube obstruction and middle ear effusion are frequent complications. Chronic allergic inflammation causes hypertrophy of tonsils and adenoids; the former may be associated with obstructive sleep apnea and the latter with eustachian tube obstruction, serous effusion, and otitis media.

Children with AR experience frustration over their appearance; some have a cognitive impairment. Pediatric Rhinoconjunctivitis Quality of Life measures in these children have documented anxiety and physical, social, and emotional issues that affect learning and the ability to integrate with peers. The disorder contributes to headaches and fatigue, limits daily activities, interferes with sleep, and leads to school absenteeism.

Chapter 134 - Childhood Asthma

Andrew H. Liu
Joseph D. Spahn
Donald Y. M. Leung

Asthma is a chronic inflammatory condition of the lung airways resulting in episodic airflow obstruction. This chronic inflammation heightens the “twitchiness” of the airways—airways hyperresponsiveness—to provocative exposures. Other associated histopathologic abnormalities of the airways characteristic of asthma include epithelial damage, subepithelial collagen deposition with basement membrane thickening, and mucus gland and smooth muscle hypertrophy. These pathologic changes, linked to persistent airways inflammation and hyperresponsiveness, form the chronic basis of this disease.

Clinical manifestations of asthma are intermittent. Dry coughing, expiratory wheezing, chest tightness, and dyspnea are commonly provoked by physical exertion and airways irritants (e.g., cold and dry air, environmental tobacco smoke). Asthma symptoms are usually associated with widespread but variable airflow obstruction that is generally reversible either spontaneously or with treatment. Asthma exacerbations for prolonged periods (i.e., from days to weeks) are induced by common respiratory viral infections and by inhalant allergen exposure in sensitized asthmatics. These exacerbations are characteristically worse at night and can progress to severe airflow obstruction, shortness of breath, and respiratory distress and insufficiency. Rarely, severe sequelae such as hypoxic seizures, respiratory failure, and death can occur.

Current asthma management is aimed at reducing airways inflammation by using daily “controller” anti-inflammatory medications, minimizing proinflammatory environmental exposures, and controlling co-morbid conditions that can worsen asthma. Less inflammation typically leads to better asthma control, including less need for “quick-reliever” asthma medication (i.e., ß-agonist bronchodilators) and fewer exacerbations. Exacerbations can, nevertheless, still occur. Early intervention with systemic glucocorticoids can greatly reduce the severity of such episodes. Thus, in contrast to past images of debilitated and frail asthmatic children, recent improvements in asthma management and especially pharmacotherapy enable all but the rare child with severe asthma to live normally. With good asthma management, almost all children with asthma can (1) attend school regularly, (2) participate fully in the sport of their choice, (3) sleep well without disturbance due to asthma, (4) experience little to no adverse effects from asthma pharmacotherapy, and (5) with early intervention, stay safe by keeping asthma exacerbations from becoming severe.

Etiology.

Although the cause of childhood asthma has not been pinpointed, contemporary research implicates an interplay between genetic and environmental factors. The strong association

of common childhood asthma with concomitant allergies suggests that environmental factors influence immune development toward the asthmatic phenotype in susceptible individuals.

GENETICS.

Twin studies have revealed a 0.74 concordance of asthma between monozygotic twins and a 0.35 concordance between dizygotic twins, implicating a genetic contribution to asthma development. More than 22 loci on 15 autosomal chromosomes have been linked to asthma. Although the genetic linkages to asthma have sometimes differed between cohorts, asthma has been consistently linked with loci containing proallergic, proinflammatory genes (e.g., the IL-4 gene cluster on chromosome 5). Genetic variation in receptors for different asthma medications is associated with variation in biologic response to these medications (e.g., polymorphisms in the glucocorticoid, ß-adrenergic, and leukotriene receptors). Accordingly, asthma pharmacogenomics should optimize asthma pharmacotherapy in the future by genotyping patients to predict their response to different asthma medication options.

ENVIRONMENT.

Common viral infections of the respiratory tract, such as with respiratory syncytial virus (RSV), can induce small airways bronchiolitis. RSV is a common cause of severe bronchiolitis and/or pneumonia in the first 2 yr of life. It is also a common precipitant of asthma exacerbations at any age. Interestingly, whereas nearly all children by age 2 yr have immunologic evidence of previous RSV infection, only 12–40% of those infected report bronchiolitis symptoms. This implies that host features affect the extent of airways injury from viral pathogens. Likewise, injurious viral infections of the airways (i.e., manifesting as pneumonia and/or bronchiolitis requiring hospitalization) are risk factors for persistent asthma in childhood.

Some airways exposures besides viral infections can exacerbate ongoing airways inflammation and increase disease severity. Allergen exposure, in sensitized individuals, can initiate airways inflammation and hypersensitivity to other irritant exposures as well. Indeed, perennial allergen exposure in sensitized asthmatics is a major contributor to disease severity. Consequently, eliminating the offending allergen(s) can lead to resolution of asthma symptoms and can sometimes “cure”

asthma. Environmental tobacco smoke, endotoxin, and air pollutants (e.g., ozone, sulfur dioxide) aggravate airways inflammation and increase asthma severity. Cold dry air and strong odors can trigger bronchoconstriction when airways are irritated but do not worsen airways inflammation or hyperresponsiveness.

Epidemiology.

Asthma is a common chronic disease, causing considerable morbidity. Based on information collected by the United States National Center for Health Statistics in 1998, 8.65 million children (12.1%) were reported to have physician- or health care professional–diagnosed asthma in their lifetime, and 3.8 million children (5.3%) had experienced an asthma episode in the preceding 12 mo. Childhood asthma in the United States is the most common cause of childhood emergency department visits, hospitalizations, and missed school days, accounting annually for 867,000 emergency department visits, 166,000 hospitalizations, and 10.1 million school days lost. Although death due to asthma is relatively uncommon in children (0.3 deaths per 100,000 population per year), asthma was responsible for 164 deaths of children in the United States in 1998. Many of these asthma deaths could probably have been avoided. Indeed, asthma is generally an underdiagnosed and undertreated condition.

In the United States, asthma morbidity and mortality are particularly high in African-American children. Asthma hospitalization and death rates are more than three times higher in black versus white Americans. A combination of biologic, environmental, economic, and psychosocial risk factors is believed to increase the likelihood of severe asthma exacerbations for ethnic minority asthmatics living in U.S. “inner-city” low-income communities. Although asthma prevalence is slightly higher in black versus white U.S. children (i.e., in 1998, 16.1% vs. 13.2%, respectively), asthma prevalence is not believed to differ significantly with either ethnicity or income status. Therefore, asthma morbidity and mortality is linked with ethnic minority and low-income status whereas asthma prevalence is primarily associated with urban living.

Worldwide, childhood asthma appears to be increasing in prevalence, despite considerable improvements in our management and pharmacopeia to treat asthma. For example, in the United States from 1982 to 1994, childhood asthma prevalence increased 72%. Numerous studies conducted in different countries have reported a similar increase in asthma prevalence of about 50% per decade. Of further interest, childhood asthma prevalence varies widely in different locales. A large international study of childhood asthma prevalence (by report) in 56 countries (International Study of Asthma and Allergies in Childhood) found about a 20-fold variation in asthma prevalence (range, 1.6–36.8%). Furthermore, asthma prevalence correlated well with reported allergic rhinoconjunctivitis and atopic eczema prevalence ($R = 0.75$ and 0.74, respectively; $p < .0001$). Childhood asthma seems particularly common in modern metropolitan locales and is strongly linked with other allergic conditions. In contrast, children living in rural areas of developing countries (e.g., rural Africa, China, India) and farming communities (e.g., in Germany, Austria, Switzerland, Finland, Quebec) are less likely to have asthma and allergy. This striking variation in childhood asthma prevalence has led to investigations of potential environmental and lifestyle factors that may explain these differences as well as the recent rise in asthma (see Chapter 130).

Approximately 80% of asthmatics report disease onset before 6 yr of age. However, of all young children who experience recurrent wheezing, only a minority will go on to have persistent asthma in later childhood. Several risk factors for persistent asthma have been identified (Box 134–1). Allergy in these young wheezers has emerged as a major risk factor for persistent childhood asthma and may be evident in the early childhood years as clinical conditions (atopic dermatitis, allergic rhinitis, food allergies).

There are two main types of childhood asthma: (1) recurrent wheezing in early childhood, primarily triggered by common viral infections of the respiratory tract, and (2) chronic asthma associated with allergy that persists into later childhood and often adulthood. A third emerging type of childhood asthma typically occurs in females who develop obesity and early-onset puberty (by 11 years of age). Although asthma mediated by “occupational” exposures is often not considered, some children are raised in settings, on farms or with farm-type animals in the home, where occupational-type exposures can mediate a fourth type of childhood asthma. **Triad asthma,** characteristically

associated with hyperplastic sinusitis/nasal polyposis and hypersensitivity to aspirin and nonsteroidal anti-inflammatory medications (e.g., ibuprofen), rarely has its onset in childhood. Current evidence suggests that, of these different types of childhood asthma, the most common form is that associated with allergy. Additionally, allergen sensitization and exposure is associated with more severe asthma.

Pathogenesis.

The pathologic changes linked to persistent airways inflammation and hyperresponsiveness underlie the chronic basis of asthma.

AIRWAYS OBSTRUCTION.

Airflow obstruction in asthma is the result of numerous pathologic processes. In the small airways, airflow is regulated by smooth muscle encircling the airways lumens; bronchoconstriction of these bronchiolar muscular bands restricts or blocks airflow. A cellular inflammatory infiltrate distinguished by eosinophils, but also including other inflammatory cell types (neutrophils, monocytes, lymphocytes), can fill the airways and induce epithelial damage and desquamation into the airways lumen. Excess production of mucus into the airways and edema of the surrounding tissues also contribute to blockage of airways.

AIRWAYS INFLAMMATION, HYPERRESPONSIVENESS, AND REMODELING.

Asthmatic airways tissues have increased numbers of mast cells, activated eosinophils, and activated helper T lymphocytes (see Chapter 130). Helper T lymphocytes that produce proallergic, proinflammatory cytokines (e.g., IL-4, IL-5, IL-13) and chemokines (e.g., RANTES, eotaxin) mediate this inflammatory process. Other immune cells (e.g., cytotoxic T lymphocytes, NK cells, eosinophils, mast cells, basophils) can produce these proallergic, proinflammatory cytokines and chemokines as well. Airways inflammation is strongly linked to hypersensitivity of airways smooth muscle **(airways hyperresponsiveness)** to irritant exposures, such as cold air, dry air, strong odors, and particulate matter in smoke.

Airways inflammation is also linked to less reversible airways changes, such as basement membrane thickening, subepithelial collagen deposition, and smooth muscle and mucus gland hypertrophy and hyperplasia. These airways “remodeling” abnormalities resemble an aberrant tissue repair process in response to persistent tissue injury. Therefore, persistent airways inflammation and remodeling are believed to underlie the chronic functional and pathologic abnormalities as well as the intermittent and episodic clinical manifestations of asthma.

Inhaled allergen challenge studies have revealed two distinct phases of airflow obstructive processes in asthma: (1) an **early phase** (within 15–30?min) consisting of bronchoconstriction and (2) a **late phase** (4–12?hr after allergen exposure) of tissue inflammation and immune cellular infiltration into the airways, in addition to airways edema and excess mucus production. The late phase is also associated with airways hyperresponsiveness that can persist for several weeks. The early phase can be prevented with inhaled ß-agonist bronchodilator pretreatment; in contrast, the late phase can be prevented with anti-inflammatory agents (e.g., glucocorticoids) but not ß-agonists. Therefore, a quick recovery after an acute allergen-induced exacerbation does not mean that the episode is over; on the contrary, a more serious and sustained late-phase episode can occur hours later.

PROGRESSION OF SEVERE ASTHMA EXACERBATIONS.

Airflow obstruction during asthma exacerbations can become extensive, resulting in life-threatening respiratory insufficiency. Often, asthma exacerbations worsen at night (i.e., between midnight to 8 am), when airways inflammation and hyperresponsiveness are at their peak. Complications that can occur during severe exacerbations include atelectasis and air leaks in the chest (pneumomediastinum or pneumothorax).

Importantly, the first-line pharmacotherapy, ß-agonists, can increase pulmonary blood flow through obstructed, unoxygenated areas of the lungs, causing ventilation-perfusion mismatching, and precipitating hypoxemia. Hypoxia perpetuates bronchoconstriction, which further worsens the condition. Severe and progressing asthma exacerbations clearly need to be managed in a medical setting, with administration of supplemental oxygen as first-line therapy.

Clinical Manifestations and Diagnosis.

Chronic symptoms are a key aspect of asthma. The medical history typically provides key information in diagnosing asthma. Intermittent dry coughing and/or expiratory wheezing are the most common chronic symptoms of asthma. Older children and adults will report associated shortness of breath and chest tightness; younger children are more likely to report intermittent, nonfocal chest “pain.” Respiratory symptoms are characteristically worse at night, especially during prolonged exacerbations triggered by respiratory infections or inhalant allergens. Other asthma symptoms in children can be subtle and include decreased physical activity, general fatigue (possibly due to sleep disturbance), and difficulty keeping up with peers in physical activities. Asking about previous experience with asthma medications (i.e., bronchodilators) may provide a history of symptomatic improvement with treatment that supports the diagnosis of asthma. Lack of improvement with bronchodilator and corticosteroid therapy is inconsistent with underlying asthma and should prompt more vigorous consideration of asthma-masquerading conditions.

Asthma symptoms are typically provoked by numerous common events or exposures: physical exertion and hyperventilation (e.g., laughing), cold or dry air, and airways irritants (Box 134–2). Exposures that induce airways inflammation, such as viral infections and inhaled allergens, also increase airways hyperresponsiveness to

irritant exposures. Numerous occupational exposures incite asthma in some adults. Similarly, some children might be chronically exposed to these same airways sensitizers in their home or school environments, leading to “occupational” asthma in children. Accordingly, an environmental history is essential to optimal asthma diagnosis (see Chapter 131) and management.

The presence of risk factors, such as a history of other allergic conditions (allergic rhinitis, allergic conjunctivitis, atopic dermatitis,

and food allergies), parental asthma, and/or asthma symptoms apart from colds, supports the diagnosis of asthma. Because numerous conditions can mimic asthma, the process of excluding common asthma masqueraders such as chronic rhinosinusitis and gastroesophageal reflux should begin in the medical history.

During routine clinic visits, children with asthma commonly present without abnormal signs. Some may exhibit a dry, persistent cough. By auscultation, the chest examination is also often normal. When breath sounds are abnormal, expiratory high-pitched polyphonic wheezing is typically heard by auscultation and is sometimes even audible without a stethoscope. Deeper breaths can sometimes elicit otherwise undetectable wheezing. The physical examination in asthmatics is also helpful in identifying co-morbid conditions (e.g., allergic rhinoconjunctivitis, rhinosinusitis, atopic dermatitis) and abnormalities consistent with other asthma-masquerading conditions (Box 134–3).

During asthma exacerbations, expiratory wheezing and a prolonged expiratory phase can usually be appreciated by auscultation. Decreased breath sounds in some of the lung fields, commonly the right lower posterior, are consistent with regional hypoventilation owing to airways obstruction. Crackles, or rales, and rhonchi can also be heard resulting from excess mucus production and inflammatory exudate in the airways. The combination of segmental crackles and poor breath sounds can

indicate lung segmental atelectasis that is difficult to distinguish from bronchial pneumonia and can complicate

acute asthma management. In severe exacerbations, the greater degree of airways obstruction causes increased work of breathing and respiratory distress manifested as inspiratory and expiratory wheezing, suprasternal and intercostal retractions, nasal flaring, and accessory respiratory muscle use.

DIFFERENTIAL DIAGNOSIS.

Many childhood respiratory conditions can present as symptoms and signs similar to asthma (see Box 134–3). Besides asthma, other common causes of chronic, intermittent coughing and/or wheezing include rhinosinusitis and gastroesophageal reflux (GER). Both GER and chronic sinusitis can be challenging to diagnose in children. GER is often clinically silent in children, and children with chronic sinusitis typically do not report sinusitis-specific symptoms such as localized sinus pressure or tenderness. In addition, both GER and rhinosinusitis are often co-morbid conditions with childhood asthma.

In early life, chronic coughing and wheezing can indicate a congenital anatomic abnormality of the airways, foreign body aspiration, recurrent aspiration, cystic fibrosis, or bronchopulmonary dysplasia. In adolescents, vocal cord dysfunction (VCD) can present as intermittent daytime wheezing. In this condition, the vocal cords close inappropriately, during inspiration and sometimes expiration, producing shortness of breath, coughing, throat tightness, and often audible laryngeal wheezing and/or stridor. In most VCD cases, spirometric lung function testing will reveal “truncated” and inconsistent inspiratory and expiratory flow-volume loops, a pattern that differs from the reproducible pattern of airflow limitation in asthma that improves with bronchodilators. However, VCD can also co-exist with asthma. Flexible rhinolaryngoscopy in the symptomatic VCD patient can reveal paradoxical vocal cord movements, with anatomically normal vocal cords. This condition can be well managed with specialized speech therapy training in the relaxation and control of vocal cord movement. Furthermore, treatment of underlying causes of vocal cord irritability (e.g., GER/aspiration, rhinosinusitis, and asthma) can improve VCD. During acute VCD exacerbations, inhalation of heliox (a mixture of 70% helium with 30% oxygen) can relieve vocal cord spasm and VCD symptoms.

In some locales, hypersensitivity pneumonitis (e.g., farming communities, homes of bird owners), pulmonary parasitic infestations (e.g., rural areas of developing countries), or tuberculosis may be common causes of chronic coughing and/or wheezing. Rare asthma-masquerading conditions at any childhood age include bronchiolitis obliterans, interstitial lung diseases, primary ciliary dyskinesias, humoral immune deficiencies, allergic bronchopulmonary mycoses, congestive heart failure, mass lesions in or compressing the larynx, trachea, or bronchi, and medication-induced coughing and/or wheezing as an adverse effect.

Laboratory Findings.

Lung or pulmonary function tests including bronchoprovocation challenges are the basis of documenting the presence of asthma and the severity of acute exacerbations.

LUNG FUNCTION TESTING.

Measures of expiratory airflow are helpful in diagnosing and monitoring asthma and in assessing efficacy of therapy. Lung function testing is particularly helpful in asthmatics who are poor perceivers of airflow obstruction or when physical signs of asthma do not occur until airflow obstruction has become severe.

Spirometry measures airflow and lung volumes during a forced expiratory maneuver and is considered the gold standard measure of airflow in asthma. Its helpfulness as an objective measure in the initial evaluation and management of asthmatics has led to recommendations for its standard use in the U.S. National Asthma Education and Prevention Program (NAEPP) guidelines sponsored by the U.S. National Institutes of Health. In asthma, airways blockage results in reduced airflow and smaller partial-expiratory lung volumes (Fig. 134–1). Of these measures, normative values for FEV_1 (forced expiratory volume

Figure 134-1 Spirometry. *A*, Spirometric flow-volume loops. A is an expiratory flow-volume loop of a nonasthmatic, without airflow limitation. B through E are expiratory flow-volume loops in asthmatic patients with increasing degrees of airflow limitation (B is mild; E is severe). Note the “scooped” or concave appearance of the asthmatic expiratory flow-volume loops; with increasing obstruction, there is greater “scooping.” *B*, Spirometric volume-time curves. Subject 1 is a nonasthmatic; subject 2 is an asthmatic. Note how the FEV_1 and FVC lung volumes are obtained. The FEV_1 is the volume of air exhaled in the 1st second of a forced expiratory effort. The FVC is the total volume of air exhaled during a forced expiratory effort. Note that subject 2's FEV_1 and FEV_1 /FVC ratio are smaller than subject 1's, demonstrating airflow obstruction. Also, subject 2's FVC is very close to what is expected.

in 1?sec) have been standardized for children, based on height, gender, and ethnicity. The reductions in FEV_1 as a percentage of predicted is one of four criteria used to determine asthma severity in the NAEPP guidelines. Because asthmatics are typically hyperinflated, often profoundly, FEV_1 can be simply adjusted for full expiratory lung volume, the forced vital capacity (FVC), with an FEV_1 /FVC ratio. Generally, an FEV_1 /FVC ratio less than 0.8 indicates significant airflow obstruction (Box 134–4). Such measures of airflow alone, however, are not diagnostic of asthma, because numerous other conditions can cause airflow reduction. Bronchodilator response to inhaled ß-agonist medication (i.e., albuterol by nebulizer) is greater in asthmatics vs. nonasthmatics—an improvement in FEV_1 greater than 12% is consistent with asthma. Importantly, valid spirometric measures are dependent on a patient's ability to properly execute a full, forced, and prolonged expiratory maneuver, typically feasible in children older than 6 yr of age (with some younger exceptions). Reproducible spirometric efforts are an indicator of test validity. If, on three consecutive attempts, the FEV_1 is within 5%, then the best FEV_1 effort of the three is used.

Bronchoprovocation challenges can be helpful in diagnosing asthma and

optimizing asthma management. Asthmatic airways are hyperresponsive and therefore more sensitive to inhaled methacholine, histamine, and cold or dry air. The degree of airways hyperresponsiveness to these exposures correlates with asthma severity and airways inflammation. Although bronchoprovocation challenges are carefully dosed and monitored in an investigational setting, their use is rarely practical in a general practice setting. **Exercise challenges** (i.e., aerobic exertion or "running" for 6–8?min) can also help to identify the child with **exercise-induced bronchospasm**. Although the airflow response of nonasthmatics to exercise is to increase functional lung volumes and improve FEV_1 slightly (5–10%), exercise typically induces airflow obstruction in untreated asthmatics. Accordingly, in asthmatics, FEV_1 typically decreases during or after exercise by more than 15% (see Box 134–4). The onset of exercise-induced bronchospasm is usually within 15?min after a vigorous exercise challenge and can spontaneously resolve within 60?min. Studies of U.S. school-age children using such exercise challenges typically identify about 10% with exercise-induced bronchospasm but previously undiagnosed asthma, in addition to the known asthmatics with exercise-induced bronchospasm. Exercise challenges can induce

* Main criteria consistent with asthma.

severe asthma exacerbations in at-risk patients; therefore, careful patient selection for exercise challenges, and preparedness for severe asthma exacerbations, is required.

Peak expiratory flow (PEF) monitoring devices provide a simple and inexpensive home-use tool to measure airflow and can be particularly helpful in many circumstances. PEFs vary in their ability to detect airflow obstruction, and, in some patients, PEF declines only when airflow obstruction is severe. Therefore, PEF monitoring should be started by measuring morning and evening PEFs (best of three consecutive attempts) for several weeks for patients to practice the technique, to determine a "personal best," and to correlate PEF values with symptoms (and ideally spirometry). PEF morning-to-evening variation greater than 20% is consistent with asthma (Fig. 134–2 and see Box 134–4).

Figure 134-2 Peak flow monitoring. *A*, Peak expiratory flows (PEFs) performed and recorded twice daily, in the morning (am) and evening (pm), over 1 mo in an asthmatic child. This child's "personal best" PEF is 220?L/min; therefore, *green zone* (<80–100% of best) is 175–220?L/min; *yellow zone* (50–80%) is 110–175?L/min; and *red zone* (<50%) is less than 110?L/min. Note that this child's pm PEFs are almost always in the green zone, whereas his am PEFs are often in the yellow or red zone. This illustrates the typical diurnal am-to-pm variation of inadequately controlled asthma. *B*, PEFs performed twice daily, in the morning (am) and evening (pm), over 1 mo in an asthmatic child who developed a viral respiratory tract infection. Note that the child's PEF values were initially in the green zone. A viral respiratory tract infection led to asthma worsening, with a decline in PEF to the yellow zone that continued to worsen until PEFs were in the red zone. At that point, a 4-day prednisone course was administered, followed by improvement in PEF back to the green zone.

RADIOLOGY.

Chest radiographs (posteroanterior and lateral views) in children with asthma often appear to be normal, aside from subtle and nonspecific findings of hyperinflation (e.g., flattening of the diaphragms) and peribronchial thickening. Chest radiographs are helpful in identifying abnormalities that are hallmarks of asthma masqueraders (e.g., aspiration pneumonitis, hyperlucent lung fields in bronchiolitis obliterans), and complications during asthma exacerbations (e.g., atelectasis, pneumothorax). Some lung abnormalities can be better appreciated with high-resolution, thin-section chest CT scans. For example, bronchiectasis is sometimes difficult to appreciate on chest radiograph but is clearly seen on CT scan and implicates asthma masqueraders such as cystic fibrosis, allergic bronchopulmonary mycoses (e.g., aspergillosis), ciliary dyskinesias, or immune deficiencies.

Other tests, such as allergy testing to assess sensitization to inhalant allergens, help with the management and prognosis of asthma. In a comprehensive U.S. study of 5–12 yr old asthmatic children (Childhood Asthma Management Program [CAMP]), 88% had inhalant allergen sensitization by allergy prick skin testing.

Treatment.

The goals of childhood asthma management for children can be simply stated (Box 134–5). The NAEPP guidelines have been adapted for childhood asthma in a joint publication of the American Academy of Allergy, Asthma & Immunology and the U.S. National Institutes of Health's National Heart, Lung and Blood Institute and the American Academy of Pediatrics entitled *Pediatric Asthma: Promoting Best Practice*. These guidelines describe four components to optimal asthma management (Box 134–6).

REGULAR ASSESSMENT AND MONITORING.

Asthma management can be optimized through regular clinic visits every 2–4 wk until good asthma control is achieved. Two to four regular annual asthma check-ups are recommended to maintain good asthma control. During these visits, asthma control can be assessed by asking about (1) the frequency of asthma symptoms during the day, at night, and with physical exercise; (2) the frequency of “rescue” short-acting ß-agonist medication use and refills; (3) the number and severity of asthma exacerbations since the last visit; and (4) participation in school, sports, and other preferred activities. Lung function testing (i.e., spirometry) is recommended annually, and more often if asthma is inadequately controlled. PEF monitoring at home can be especially helpful when assessing asthmatic children with poor symptom perception, other causes of chronic coughing in addition to asthma, moderate-to-severe asthma, or a history of severe asthma exacerbations. PEF monitoring is feasible in children as young as 4 yr old and who are able to master this skill. Use of a “stoplight” zone system, preferably tailored to each child's best PEFs, can optimize effectiveness and interest (see Fig. 134–2): the green zone (80–100% of predicted or the child's best) indicates good control, the yellow zone (50–80%) indicates less than optimal control and necessitates increased awareness and treatment, whereas the red zone (<50%) indicates poor control requiring immediate intervention. The NAEPP guidelines recommend once-daily PEF monitoring, preferably in the morning.

CONTROL OF FACTORS CONTRIBUTING TO ASTHMA SEVERITY.

Controllable factors that can significantly worsen asthma can be generally grouped as (1) environmental exposures and (2) co-morbid conditions (Box 134–7).

Eliminate or Reduce Problematic Environmental Exposures. The majority of children with asthma have an allergic component to their disease. Because of this, steps should be taken to investigate and minimize allergen exposures in sensitized asthmatics. Several studies have shown that, in sensitized asthmatics, reduced exposure to allergens can decrease asthma symptoms, the need for medications, and airways hyperresponsiveness.

Asthmatic children who are sensitized to indoor allergens in particular can experience greater asthma severity due to year-round exposure and can benefit from measures to minimize

Box 134-5. Goals of Childhood Asthma Management

- Maintain normal activity
    - Regular school or daycare attendance
    - Full participation in physical exercise, athletics, and other recreational activities
- Prevent sleep disturbance
- Prevent chronic asthma symptoms
- Keep asthma exacerbations from becoming severe
- Maintain normal lung function
- Experience little to no adverse effects of treatment

Gastroesophageal reflux

GET ANNUAL INFLUENZA VACCINATION (UNLESS EGG-ALLERGIC)

allergen exposure in the home. Common perennial allergen exposures include furred or feathered animals as pets or as pests and occult indoor allergens such as dust mites, molds, and cockroaches. Although some sensitized children may report an increase in asthma symptoms on exposure to the allergen source, improvement from allergen avoidance may not become apparent without a sustained period of days to weeks away from the offending exposure. Tobacco, wood, and coal smoke, dusts, and strong or noxious odors and fumes can all aggravate asthma. At the very least, these airways irritants should be eliminated or reduced from the homes and automobiles used by asthmatic children. School classrooms and daycare centers can also be sites of asthma-worsening environmental exposures. Eliminating or minimizing these exposures can reduce asthma symptoms, disease severity, and the amount of medication needed to achieve good asthma control. Common viral infections of the respiratory tract are difficult to avoid; annual influenza vaccination is recommended for all asthmatic children (except for those with egg allergy).

Treat Co-morbid Conditions. Rhinitis, sinusitis, and gastroesophageal reflux commonly accompany asthma and can worsen disease severity. Indeed, these conditions are also common causes of chronic coughing. Effective management of these co-morbid conditions can often improve asthma symptoms and

disease severity, so that less medication is needed to achieve good asthma control.

Gastroesophageal reflux (GER) is commonly noted in asthmatics, with a reported incidence of up to 64%. GER may worsen asthma through two postulated mechanisms: (1) aspiration of refluxed gastric contents (micro- or macroaspiration) and (2) reflex bronchospasm. GER should be suspected in all individuals with difficult-to-control asthma, especially patients with prominent symptoms while eating or sleeping (i.e., in a horizontal position). GER can be confirmed by demonstration of reflux of barium into the esophagus during a barium swallow procedure or by esophageal pH monitoring. Because radiographic studies lack sufficient sensitivity and specificity, extended esophageal pH monitoring is the method of choice for diagnosing GER. If significant GER is noted, reflux precautions should be instituted (no food 2?hr before bedtime, head of the bed elevated 6?in) and antacid medications such as H_2 -receptor antagonists (e.g., cimetidine, ranitidine) or proton pump inhibitors (e.g., omeprazole, lansoprazole), and possibly pro-kinetic

pharmacotherapy, administered for a 6–8 wk period.

Radiographic evidence for sinus disease is also common in patients with asthma. Several case series have reported significant improvement in asthma control in patients diagnosed and treated for occult sinus disease. A screening CT scan of the sinuses is the current gold standard test for sinus disease. If the patient with asthma has clinical and radiographic evidence for sinusitis, topical therapy to include nasal saline irrigations and intranasal glucocorticoids should be instituted, and a 3 wk course of antibiotics administered.

PRINCIPLES OF ASTHMA PHARMACOTHERAPY.

The NAEPP guidelines classify asthma severity before treatment using four parameters: (1) frequency of daytime or (2) nighttime symptoms, (3) degree of airflow obstruction by spirometry, and/or (4) PEF variability (Table 134–1). Asthmatics can be categorized in four disease severity groups, as “mild intermittent” or “persistent” disease that is “mild,” “moderate,” or “severe.” A major objective of this approach is to identify and treat all “persistent” asthma with anti-inflammatory controller medication. The “3 Strikes” rule is a handy memory aid for determining if an asthmatic child should receive controller therapy based on the NAEPP guidelines. Simply put, if an asthmatic child has asthma symptoms or requires quick-relief medication more than three times per week, awakens at night due to asthma more than three times per month, or requires a refill for a quick-relief inhaler prescription more than three times per year, then that patient should receive daily controller therapy. Low-dose inhaled glucocorticoids, leukotriene pathway modifiers, or cromolyn/nedocromil are the recommended controllers for mild persistent asthmatics; sustained-release theophylline is an alternative. The recommended controller medication for moderate persistent asthmatics is medium-dose inhaled glucocorticoids or low-dose inhaled glucocorticoids in combination with a long-acting ß-agonist or a leukotriene pathway modifier; sustained release theophylline or long-acting oral ß-agonists are alternatives. Severe persistent asthmatics should receive high-dose inhaled glucocorticoids, a long-acting bronchodilator, and routine oral glucocorticoids if needed. “Mild intermittent asthma” is the only level of asthma severity where daily controller therapy

TABLE 134-1 -- **Stepwise Approach for Managing Asthma: Severity Classification and M**

Asthma Severity	Days with Symptoms	Nights with Symptoms	Lung Function	Long-Term-Control Medication	Quick-Relief Medication
Step 1: Mild Intermittent	<3 per wk	<3 per mo	FEV_1 or PEF =80% of predicted; PEF variability <20%	No daily medication needed	**Short-acting ß-agonist** as needed and before exercise; Use =3 times per wk may indicate need to initiate long-term-control therapy

Step 2: Mild Persistent	=3 per wk	3–4 per mo	FEV_1 or PEF =80% of predicted; PEF variability 20–30%	**Anti-inflammatory:** either low-dose **inhaled glucocorticoid, cromolyn, nedocromil, or leukotriene modifier.** Sustained-release theophylline is an alternative.	**Short-acting ß-agonist** as needed and before exercise; daily use or increasing use may indicate need for additional long-term-control therapy
Step 3: Moderate Persistent	Daily symptoms, daily use of short-acting ß-agonists	>1 time per wk	FEV_1 or PEF >60 and =80% of predicted; PEF variability >30%	**Anti-inflammatory: inhaled glucocorticoids** (medium-dose) or inhaled glucocorticoids (low-dose) and either **long-acting ß-agonist (LABA), leukotriene modifier,** sustained-release theophylline, or LABA tablets.	**Short-acting ß-agonist** as needed and before exercise; daily use or increasing use may indicate need for additional long-term-control therapy
Step 4: Severe Persistent	Continual symptoms, limited physical activity, frequent exacerbations	Frequent	FEV_1 or PEF =60% of predicted; PEF variability >30%	**Anti-inflammatory: inhaled glucocorticoids** (high-dose) and long-acting bronchodilator: either **LABA, leukotriene modifier,** sustained-release theophylline, and/or LABA tablets. Oral glucocorticoid if needed.	**Short-acting ß-agonist** as needed and before exercise; daily use or increasing use may indicate need for additional long-term-control therapy

Modified from the National Asthma Education & Prevention Program: Expert Panel Report II: Guid Diagnosis and Management of Asthma. *Bethesda, MD, National Institutes of Health, National Hea Blood Institute, 1997*

* *Based on clinical features before treatment; classification is determined by the patient's most severe feature; bold print indicates preferred medication;* ***asthmatics with "persistent" disease of any severity should be treated with a "long-term-control" anti-inflammatory medication***

is not recommended. In these subjects, short-acting inhaled ß-agonists are recommended as needed for symptoms and for exercise pre-treatment for those with exercise-induced bronchospasm. Short-acting ß-agonists are the recommended reliever medication for all asthma severity levels. They are to be used as needed for acute symptoms.

"Step-Up, Step-Down" Approach. The NAEPP guidelines outline a stepwise approach to asthma therapy that emphasizes initiating higher-level controller therapy at the outset to establish prompt control, with measures to "step-down" therapy once good asthma control is achieved.

Inhalation Technique. Optimal inhalation technique for each puff of metered-dose inhaler (MDI)-delivered medication is a slow (5?sec) inhalation, then a 5–10?sec breath hold. No waiting time between puffs of medication is needed. Spacer devices for the delivery of all medications from MDIs should be used universally in all children with asthma. **Spacer devices** are simple and inexpensive tools that serve three major functions: (1) they decrease the amount of coordination required to use MDIs, especially in young children; (2) they improve the delivery of inhaled drug to the lower airways, which in turn improves medication efficacy; and (3) they minimize the risk of systemic absorption of inhaled glucocorticoids, thus minimizing potential adverse effects of this class of medications. Mouth rinsing is recommended after inhaled glucocorticoid use to rinse out inhaled glucocorticoids deposited on the oral mucosa.

Combination Pharmacotherapy. Most children will have their asthma well controlled on a single controller medication. In children who continue to be symptomatic on low to moderate doses of inhaled glucocorticoid therapy, studies have shown a superior outcome when a long-acting ß-agonist or leukotriene pathway modifier is added to the original dose of inhaled glucocorticoids rather than doubling the dose of the inhaled glucocorticoid. Thus, lung function and asthma control can be optimized without increasing the potential for systemic effects from inhaled glucocorticoids.

Adherence. Asthma is a chronic condition that is often best managed with daily controller medication. However, adherence with a daily regimen can be suboptimal. A study that evaluated adherence of asthmatic children to routine inhaled glucocorticoids found that they were underused 60% of the time. In addition, individuals who required an oral glucocorticoid burst due to an asthma exacerbation had used their inhaled glucocorticoids the least (<15% of the time). Other studies have found that adherence is poorer when prescribed frequency of medication administration is greater (i.e., 3–4 times/24?hr). Therefore, treatment strategies should be designed to minimize the frequency with which medications are administered (i.e., once or twice daily).

QUICK-RELIEF OR RELIEVER MEDICATIONS.

Asthma medications are used as quick-relief, or "reliever" or "rescue," medications, or long-term-control, or "controller," medications (Table 134–2). Quick-relief

medications (inhaled ß$_2$ -agonists, inhaled anticholinergics, and short-course systemic glucocorticoids) are used in the management of acute episodes of bronchospasm.

Short-Acting ß$_2$ -Agonists. Given their rapid onset of action, effectiveness, and 4–6?hr duration of action, inhaled short-acting ß-agonists (e.g., albuterol, levalbuterol, terbutaline, pirbuterol) are the drugs of choice for acute episodes of bronchospasm (i.e., “rescue” medications) and for preventing exercise-induced bronchospasm. ß-Agonists bronchodilate by inducing airway smooth muscle relaxation, reducing vascular permeability airways edema, and improving mucociliary clearance. Studies have reported that overuse of ß-agonists is associated with increased death or near-death episodes from asthma. This is a major concern for some patients with asthma who rely on short-acting ß-agonists as a “quick fix” for their asthma, rather than using controller medications in a preventive manner.

TABLE 134-2 -- **Asthma Medications by Category**

Category	Examples of Medications
Quick-relief medications (“relievers”)	Short-acting inhaled ß-agonists:
	Albuterol (Ventolin, Proventil)
	Levalbuterol (Xopenex)
	Terbutaline (Brethaire)
	Pirbuterol (Maxair)
	Metaproterenol (Alupent)
	Inhaled anticholinergics:
	Ipratropium (Atrovent)
	Atropine
	Short-course systemic glucocorticoids:
	Prednisone (Deltasone)
	Methylprednisolone (Medrol)
	Methylprednisolone Sodium Succinate (Solu-Medrol)
Long-term-control medications (“controllers”)	Nonsteroidal anti-inflammatory agents:
	Cromolyn (Intal)
	Nedocromil (Tilade)
	Inhaled glucocorticoids:
	Beclomethasone (Vanceril, Beclovent, Qvar)
	Flunisolide (Aerobid)
	Budesonide (Pulmicort)
	Fluticasone (Flovent)
	Triamcinolone (Azmacort)
	Mometasone (Asmanex)
	Sustained-release theophylline (Slobid, Theodur, Uniphyl)
	Long-acting inhaled ß-agonists:
	Salmeterol (Serevent)
	Formoterol (Foradil)
	Leukotriene modifiers:
	Montelukast (Singulair)
	Zafirlukast (Accolate)
	Zileuton (Zyflo)
	Oral glucocorticoids (prednisone, methylprednisolone)

It is helpful to monitor the frequency of inhaled ß-agonist use, in that use of >1 canister/mo (200 inhalations/mo) indicates inadequate asthma control and necessitates initiating or intensifying controller therapy.

Anticholinergic Agents. As bronchodilators, the anticholinergic agents (e.g., ipratropium bromide) are much less potent than the ß-agonists. Inhaled ipratropium is primarily used in the treatment of acute severe asthma. When used in combination with albuterol, ipratropium has been shown to significantly improve lung function and to reduce the rate of hospitalization in children who present to the emergency department with acute asthma. Ipratropium bromide is the anticholinergic drug of choice because it has few central nervous system adverse effects, and it is available in both MDI and nebulizable formulations. Although widely used in children with asthma exacerbations of all ages, it is approved by the U.S. Food and Drug Administration (FDA) for use in children >12 yr of age.

Systemic Glucocorticoid Therapy. Short-course, systemic glucocorticoid therapy is recommended for use in moderate- to-severe asthma exacerbations, both to hasten recovery and prevent recurrence of symptoms. The efficacy of glucocorticoid therapy for asthma exacerbations in children is firmly established. Studies evaluating single doses of glucocorticoids administered in the emergency department, short courses of oral glucocorticoids in the clinic setting, and both oral and intravenous formulations in hospitalized children have all demonstrated effectiveness. Studies in children hospitalized with acute asthma have found glucocorticoids administered orally to be as effective as intravenous glucocorticoids. Accordingly, oral glucocorticoid therapy can often be used, although children in respiratory distress who require high flow rates of oxygen to adequately treat hypoxemia are obvious candidates for intravenous glucocorticoid therapy. For hospitalized children, the NAEPP guidelines recommend administering methylprednisolone at 1?mg/kg/dose every 6?hr for 48?hr, with a taper to 1–2?mg/kg/24?hr (maximum 60?mg/24?hr) in two divided doses until the patient's PEFs reach 70% of predicted or personal best. For outpatient

management of acute asthma, the NAEPP guidelines suggest 1–2?mg/kg/24?hr (maximum 60?mg/24?hr) of prednisone or methylprednisolone in a single or two divided doses for 3–10 days.

LONG-TERM-CONTROL OR CONTROLLER MEDICATIONS.

Mild to moderate persistent asthma should be treated with long-term-control medications, which include nonsteroidal anti-inflammatory agents, inhaled glucocorticoids, sustained-release theophylline, long-acting inhaled ß-agonists, and leukotriene modifiers.

Nonsteroidal Anti-inflammatory Agents. Cromolyn and nedocromil are "nonsteroidal" anti-inflammatory agents that can inhibit both the early and late phase components of allergen-induced asthmatic responses and can inhibit exercise-induced bronchospasm. Both drugs are indicated for mild to moderate asthma and are considered first-line anti-inflammatory drugs for children with mild persistent asthma according to the NAEPP guidelines. Although largely devoid of adverse effects, these medications must be administered frequently (two to four times/24?hr) and are not nearly as effective as the other two major controller classes of medications, namely, the inhaled glucocorticoids and leukotriene-modifying agents. As a result, they should now be considered alternative agents. Because they inhibit exercise-induced bronchospasm, they can be used in place of short-acting ß-agonists, especially in children who develop unwanted adverse effects with ß-agonist therapy (e.g., tremor and elevated heart rate). They can also be used in combination with short-acting ß-agonists in patients who continue to experience exercise-induced bronchospasm despite short-acting ß-agonist pretreatment.

Glucocorticoids. Glucocorticoids are available in inhaled, oral, and parenteral forms. Glucocorticoids are the most potent and effective medications used to treat both the acute (administered systemically) and chronic (administered topically) manifestations of asthma.

Inhaled Glucocorticoid Therapy. The development of inhalation devices, which effectively deliver potent glucocorticoids into the airways, have made inhaled glucocorticoid therapy the treatment of choice for patients with persistent asthma (see Table 134–1). Inhaled glucocorticoid therapy has been shown to reduce asthma symptoms, improve baseline pulmonary function, and reduce bronchial hyperresponsiveness. In addition, inhaled glucocorticoid therapy in children with mild to moderate persistent asthma results in less need for "rescue" short-acting ß-agonists use and less need for prednisone and can reduce, by up to 50%, urgent care visits and hospitalizations for acute asthma. Lastly, large epidemiologic studies have now demonstrated low-dose inhaled glucocorticoid therapy to "protect" against asthma death. Inhaled glucocorticoids achieve all of the goals of asthma therapy and as a result have become the gold standard treatment for asthma.

The NAEPP guidelines recommend low-dose inhaled glucocorticoid therapy for all patients with persistent asthma. Whether inhaled glucocorticoids should be first-line therapy in children with mild persistent asthma is controversial. Advocates for inhaled glucocorticoid therapy argue that because this medication reduces airways inflammation, bronchial hyperresponsiveness, and asthma morbidity and mortality, it should be used in all patients with persistent asthma. In contrast, others argue that since inhaled glucocorticoid therapy is not without the potential for adverse effects, its use should be reserved for those with moderate to severe persistent asthma. A few studies have suggested that delay in initiation of inhaled glucocorticoid therapy leads to a diminished therapeutic response. The implication of these studies is that asthma is a progressive condition that requires anti-inflammatory therapy to prevent airway remodeling and subsequent loss of therapeutic response.

There are currently five FDA-approved inhaled glucocorticoids, with a sixth product likely to be approved in 2002 (see Table 134–3). Inhaled glucocorticoids are available for use in MDIs with ozone-friendly propellants, as dry powder inhalers (DPIs), or in suspension for nebulization. All of the available inhaled glucocorticoids are effective in asthma. Fluticasone propionate, mometasone furoate, and, to a lesser extent, budesonide are thought to be "second generation" inhaled glucocorticoids in that they display greater topical to systemic potency compared with other available inhaled glucocorticoids, resulting in a better therapeutic index. Second-generation inhaled glucocorticoids display both increased anti-inflammatory potency and reduced systemic bioavailability, owing to extensive first-pass hepatic

metabolism, making these compounds well suited for patients with severe asthma. The NAEPP guidelines recommend starting with higher inhaled glucocorticoid doses and “stepping down” the dose as asthma control improves. Many studies have shown that a fraction of the initial glucocorticoid dose is often sufficient once asthma control is achieved. The ideal inhaled glucocorticoid dose should be large enough to control asthma symptoms yet small enough to avoid the potential for adverse systemic effects (see Table 134–3). Inhaled

TABLE 134-3 -- **Inhaled Glucocorticoids Daily Dosage Guidelines***

Glucocorticoid	Low Dose	Medium Dose	High Dose
Beclomethasone			
42, 84?µg/puff (40?µg/puff HFA–propellant)	84–336?µg (2–8 puffs of 42?µg/puff or1–4 puffs of 84?µg/puff)	336–672?µg (8–16 puffs of 42?µg/puff or 4–8 puffs of 84?µg/puff)	>672?µg (> 16 puffs of 42?µg/puff or> 8 puffs of 84?µg/puff)
Budesonide			
Turbuhaler (DPI) 200?µg/inhalation	200–400?µg (1–2 inhalations)	400–800?µg (2–4 inhalations)	> 800?µg (>4 inhalations)
Respules (nebulizer) 250, 500?µg/vial	500?µg QD	1000?µg	2000?µg
Flunisolide			
250?µg/puff (MDI)	500–750?µg (2–3 puffs)	1000–1250?µg (4–5 puffs)	> 1250?µg (>5 puffs)
Fluticasone			
44, 110, 220?µg/puff (MDI)	88–176?µg (2–4 puffs of 44?µg/puff)	176–440?µg (4–10 puffs of 44?µg/puff or2–4 puffs of 110?µg/puff or1–2 puffs of 220?µg/puff)	> 440?µg (>4 puffs of 110?µg/puff or > 2 puffs of 220?µg/puff)
Triamcinolone			
100?µg/puff (MDI with spacer)	400–800?µg (4–8 puffs)	800–1200?µg (8–12 puffs)	>1200?µg (> 12 puffs)

* *Estimated comparative daily doses for children = 12 yr of age*

glucocorticoids can be effective when administered once or twice daily.

Although inhaled glucocorticoids have been widely used in adults with persistent asthma, their use in children has been lagging. The reluctance to use inhaled glucocorticoids in childhood asthma has come primarily from their potential for adverse effects with chronic use. Generally, clinically significant adverse effects that occur with chronic systemic glucocorticoid therapy (Box 134–8) have not been seen or have been only rarely reported in children receiving inhaled glucocorticoid therapy in recommended doses. The risk of adverse effects from inhaled glucocorticoid therapy is related to the dose and frequency with which inhaled glucocorticoids are given. High doses (1,000?µg/24?hr in children) administered frequently (e.g., four times/24?hr) have an increased risk for local and systemic adverse effects.

The most commonly encountered adverse effects from inhaled glucocorticoid therapy are local and consist of oral candidiasis (thrush) and dysphonia (hoarse voice). Thrush is thought to occur as a result of local immunosuppression. Dysphonia occurs as a result of vocal cord myopathy. These effects are dose dependent and are most common in individuals on high-dose inhaled and/or oral glucocorticoid therapy. The incidence of these local effects can be greatly minimized by using a holding chamber or “spacer” when using inhaled glucocorticoids delivered via a MDI because these devices effectively

reduce the oropharyngeal deposition of the drug. Mouth rinsing using a “swish and spit” technique after inhaled glucocorticoid inhalation is also recommended after administration of any inhaled glucocorticoid.

The potential for growth suppression with long-term inhaled glucocorticoids has long been a concern among health care professionals caring for asthmatic children. Complicating this issue is the long known, but often overlooked observation that asthma, especially poorly controlled asthma, can adversely affect growth. In the long term, prospective Childhood Asthma Management Program (CAMP) study, after a mean of 4.3 yr of therapy, children with mild to moderate asthma randomized to budesonide (400?µg/24?hr) had grown 22.7?cm, whereas those randomized to placebo had grown 23.8?cm—a 1.1?cm difference. Of importance, this 1.1?cm difference occurred primarily in the first year of therapy, indicating that the growth suppression was a transient, not progressive phenomenon. Agertoft and Pedersen, in an open-label, controlled study, found no difference in the measured versus the expected adult heights in a cohort of asthmatics who had received inhaled budesonide (400?µg/24?hr) for longer than 9 yr. They also noted transient growth suppression in the first few years of therapy, with eventual catch-up growth and no adverse effect on final adult height. These two long-term studies support the contention that inhaled glucocorticoid therapy results in a modest and transient effect on growth that is unlikely to have a significant adverse effect on adult height.

Two large pediatric studies that have evaluated the effect of long-term inhaled glucocorticoids on bone mineral density failed to find a relationship between inhaled glucocorticoids use and diminished bone mineral density. Although these studies cannot predict a significant effect of inhaled glucocorticoid therapy on osteoporosis in later adulthood (i.e., after 30 yr of use), improved asthma control may result in less

glucocorticoid therapy needed over time. In summary, current evidence suggests that long-term inhaled glucocorticoid therapy has no significant effect on adult attained height or on bone mineral density. These findings were with budesonide at doses of roughly 400?µg/24?hr; higher doses of inhaled glucocorticoids will have a greater potential for adverse effects.

Systemic Glucocorticoid Therapy. Inhaled glucocorticoid therapy has allowed the majority of patients with asthma to maintain good control of their disease. Indeed, inhaled glucocorticoid therapy has allowed many patients with severe asthma to reduce or even discontinue maintenance oral glucocorticoids. Thus, oral glucocorticoid therapy is now used primarily to treat asthma exacerbations and in rare patients with severe disease who remain symptomatic despite optimal use of other asthma medications. In these severe asthmatics, every attempt should be made to exclude any co-morbid conditions and to keep the oral glucocorticoid dose at =20?mg administered on alternate days. Doses exceeding this amount are associated with numerous adverse effects (see Box 134–8). To determine the need for continued oral glucocorticoid therapy, a gradual taper of the oral glucocorticoid dose should be considered, with close monitoring of the patient's symptoms and lung function.

When administered orally, prednisone, prednisolone, and methylprednisolone are rapidly and nearly completely absorbed, with peak plasma concentrations occurring within 1–2?hr. Of interest, prednisone is an inactive pro-drug that requires biotransformation via first pass hepatic metabolism to prednisolone, its active form. Glucocorticoids are metabolized in the liver into inactive compounds, with the rate of metabolism influenced by drug interactions and disease states. Anticonvulsants (e.g., phenytoin, phenobarbital, carbamazepine) increase the metabolism of prednisolone, methylprednisolone, and dexamethasone, with methylprednisolone most significantly affected. Rifampin also enhances the clearance of glucocorticoids and can result in diminished therapeutic effect. Other medications

(e.g., ketoconazole, oral contraceptives) can significantly delay glucocorticoid metabolism. Macrolide antibiotics (e.g., erythromycin, clarithromycin) can also delay glucocorticoid clearance; however, this effect is limited to methylprednisolone.

Children who require chronically administered oral glucocorticoids are at risk of developing steroid-induced adverse effects over time (see Box 134–8). Essentially all major organ systems can be adversely affected by chronically administered oral glucocorticoid therapy. These effects can occur immediately (i.e., metabolic effects) or can develop insidiously over several months to years (e.g., growth suppression, osteoporosis, cataracts). Most adverse effects depend on the duration of treatment and occur in a cumulative dose-dependent manner.

Theophylline. Theophylline is rarely used in pediatric asthma because of its potential toxicity. Theophylline, when used chronically, can reduce asthma symptoms and need for supplemental ß-agonist use. Because theophylline may have some glucocorticoid-sparing effects in individuals with oral glucocorticoid-dependent asthma, it is still sometimes used in this group of asthmatic children. Theophylline has a narrow therapeutic window; therefore, serum theophylline levels need to be routinely monitored, especially if the patient has a viral illness associated with a fever or is placed on a medication known to delay theophylline clearance, such as macrolide antibiotics, cimetidine, oral antifungals, oral contraceptives, and ciprofloxacin. Elevated theophylline levels have been associated with headaches, vomiting, cardiac arrhythmias, seizures, and death.

Long-Acting Inhaled ß-Agonists. Salmeterol and formoterol are long-acting inhaled ß-agonists (LABAs), considered as controller medications. Neither is intended for use as a “rescue” medication for acute episodes of bronchospasm or asthma exacerbations, nor recommended as monotherapy for persistent asthma. Salmeterol has a prolonged onset of action, with maximal bronchodilation about 1?hr after administration, whereas formoterol has an onset of action within 5–10?min. Both medications have a prolonged duration of effect of at least 12?hr. Given their long duration of action, they are well suited for patients with nocturnal asthma and for individuals who require frequent use of short-acting ß-agonist inhalations during the day to prevent exercise-induced bronchospasm. Their major role is as “add-on” agents in patients who are suboptimally controlled on inhaled glucocorticoid therapy alone. Several studies have found the addition of an LABA to an inhaled glucocorticoid to be superior to doubling the dose of the inhaled glucocorticoid in subjects whose asthma is inadequately controlled on an inhaled glucocorticoid alone. These results suggest that LABAs have some inhaled glucocorticoid-sparing effects. Both LABAs are FDA approved for use in children (salmeterol: > age 4 yr; formoterol: > age 6 yr).

Leukotriene-Modifying Agents. Leukotrienes are potent proinflammatory mediators that can induce bronchospasm, mucus secretion, and airways edema. Two classes of leukotriene modifiers have been developed: inhibitors of leukotriene synthesis and leukotriene receptor antagonists. Zileuton, currently the only leukotriene synthesis inhibitor, is not approved for use in children < 12 yr of age. Because zileuton is administered four times daily, can result in elevated liver function enzymes in 2–4% of patients, and interacts with medications metabolized via the cytochrome-P450 system, it is rarely prescribed for children with asthma.

Leukotriene receptor antagonists (LTRAs) have bronchodilator and targeted anti-inflammatory properties and block exercise-, aspirin-, and allergen-induced bronchoconstriction. Two LTRAs are approved for use in children: zafirlukast and montelukast. Both medications improve asthma symptoms, decrease need for supplemental ß-agonist use, and improve pulmonary function in patients with asthma. Montelukast is administered once daily (10?mg for children = 15 yr; 5?mg for children 6–14 yr; 4?mg for children 2–5 yr). Zafirlukast is FDA approved for use in children 7 yr and older and is administered twice daily (10?mg twice daily in children 7–11 yr; 20?mg twice daily in children > 12 yr). Although incompletely studied in children with asthma, LTRAs appear to be less effective than inhaled glucocorticoids in patients with moderate persistent asthma. In general, studies have found inhaled glucocorticoids improve baseline lung function by 10–15%, whereas LTRAs improve baseline lung function by 5–7.5%. These drugs are not thought to have significant adverse effects, although recent case reports described a Churg-Strauss–like syndrome of pulmonary infiltrates, eosinophilia, and cardiomyopathy in adults with glucocorticoid-dependent asthma treated with zafirlukast. It remains to be determined whether these patients had a primary eosinophilic vasculitis masquerading as asthma, which was “unmasked” as their oral glucocorticoid dose

was tapered, or whether the disease was a rare adverse effect of the drug.

ASTHMA EXACERBATION MANAGEMENT.

Asthma exacerbations are acute or subacute episodes of progressively worsening symptoms associated with expiratory airflow obstruction. It is important to consider asthma severity based on the frequency and severity of previous asthma exacerbations and to identify asthmatics at increased risk for life-threatening exacerbations. Asthma exacerbation severity can be quantified by the number of emergency department visits, hospitalizations, and systemic glucocorticoid courses for asthma exacerbations. Previous severe asthma exacerbations, resulting in respiratory distress, hypoxia, or respiratory failure are probably the best predictors of a future life-threatening exacerbation or fatal asthma episode. Biologic, environmental, economic, and psychosocial risk factors for increased asthma morbidity and mortality have been identified (Box 134–9).

Home Management of Asthma Exacerbations. All asthmatics should have a written action plan that can help guide them in recognizing and assessing their overall asthma control and the severity of acute asthma exacerbations. Recognizing symptoms early and intensifying treatment soon after symptoms worsen

Box 134-9. Risk Factors for Asthma Morbidity and Mortality

BIOLOGIC

- Previous severe asthma exacerbation
- Severe airflow obstruction
- History of rapidly occurring attacks
- Severe airways hyperresponsiveness
- Increasing and large diurnal variation in peak flows
- Decreased chemosensitivity and perception of dyspnea
- Poor response to systemic glucocorticoid therapy
- Male gender
- Low birth weight
- Nonwhite (especially black) ethnicity

Male gender

Low birth weight

Nonwhite (especially black) ethnicity

ENVIRONMENTAL

- Allergen exposure
- Environmental tobacco smoke exposure
- Air pollution exposure
- Urban environment

ECONOMIC/PSYCHOSOCIAL

- Poverty
- Crowding
- Mother <20 yr old
- Mother with less than high school education
- Inadequate medical care
    - Inaccessible
    - Unaffordable
    - No regular medical care (only emergent)
    - No care sought for chronic asthma symptoms
    - Delay in care of asthma exacerbations
    - Inadequate hospital care for asthma exacerbation
- Psychopathology in the parent or child
- Family problems
- Alcohol or substance abuse

can often prevent further worsening and can keep exacerbations from becoming severe. One study found that having a written home action plan was associated with a 70% reduction in the risk of asthma death associated with an acute exacerbation. Clinical signs and symptoms characteristic of an acute episode include cough, shortness of breath, wheezing, chest tightness, use of accessory muscles, and suprasternal retractions. The NAEPP guidelines recommend immediate treatment with “rescue” medication (i.e., inhaled short-acting ß-agonist, up to three treatments in 1?hr). A good response is characterized by resolution of symptoms within an hour, no further symptoms over the next 4?hr, and improvement in PEF of 80% predicted or personal best. The child's physician should be contacted for follow-up, especially if bronchodilators are required repeatedly over the next 24–48?hr. If the child has an incomplete response to initial treatment with rescue medication (i.e., persistent symptoms and/or a PEF of 60–80% of predicted or personal best), a short course of oral glucocorticoid therapy (e.g., prednisone 1–2?mg/kg/24?hr for 4 days) in addition to inhaled ß-agonist therapy should be instituted. The physician should also be contacted for further instructions. Immediate medical attention should be sought for severe exacerbations, persistent signs of respiratory distress, lack of expected response or sustained improvement after initial treatment, further deterioration, or presence of risk factors for asthma morbidity or mortality. Patients should have medications such as inhaled short-acting ß-agonists, oral glucocorticoids, and equipment for treating exacerbations at home.

Emergency Department Management of Asthma Exacerbations. The primary goals of asthma management in the emergency department setting include correction of hypoxemia, rapid improvement of airflow obstruction, and prevention of progression or recurrence of symptoms. Treatment is based on clinical severity on arrival, response to initial therapy, and presence of risk factors that are associated with asthma death. Initial treatment includes close monitoring of clinical status, treatment with supplemental oxygen, inhaled ß-agonist every 20?min for 1?hr, and if necessary, systemic glucocorticoids (2?mg/kg/day) given either orally or intravenously. Inhaled ipratropium may be added to the ß-agonist treatment if no significant response is seen with the first inhaled ß-agonist treatment. A *subcutaneous* injection of epinephrine or other ß-agonist may be administered in severe cases. The patient may be discharged to home if there is sustained improvement in symptoms, normal physical findings, PEF greater than 70% of predicted or personal best, and an oxygen saturation greater than 92% on room air for 4?hr. Discharge medications include administration of an inhaled ß-agonist up to every 3–4?hr plus a 3–7 day course of oral glucocorticoids.

Hospital Management of Asthma Exacerbations. For patients with a moderate to severe asthma exacerbation that does not significantly improve within 1–2?hr after the initial treatment, associated with PEFs less than 70% or oxygen saturations less than 90–92%, admission to the hospital is warranted. Other indications for hospital admission include prolonged symptoms before the emergency department visit, inadequate access to medical care and medications, difficult psychosocial conditions, or difficulty in obtaining transportation to the hospital in event of further deterioration. Admission to an intensive care unit is indicated for patients with poor response to therapy, persistent severe respiratory distress, or evidence of impending respiratory arrest.

Supplemental oxygen, frequently administered inhaled ß-agonists, and systemic glucocorticoid therapy are the treatments of choice for children admitted to the hospital for acute asthma. Supplemental oxygen is administered because many children hospitalized with acute asthma will have hypoxemia, especially at night. Short-acting ß-agonists can be delivered frequently and, if needed, continuously. When administered continuously, significant systemic absorption of ß-agonist occurs and, as a result, continuous nebulization can obviate the need for intravenous ß-agonist therapy. Adverse effects of frequently administered ß-agonist therapy include tremor, irritability, tachycardia, and hypokalemia. Patients requiring frequent or continuous nebulized ß-agonist therapy should have continuous cardiac monitoring. Because frequent ß-agonist therapy can cause ventilation-perfusion mismatch and precipitate hypoxemia, oximetry is indicated with supplemental oxygen. Ipratropium is often added to albuterol every 6?hr, although there is little evidence to support its use in hospitalized children receiving aggressive inhaled ß-agonist therapy and systemic glucocorticoids. Patients with persistent severe dyspnea and high-flow oxygen requirements will often require intravenously administered fluids. In this situation, administration of fluids at or slightly below maintenance fluid requirements is recommended, owing to increased antidiuretic hormone (ADH) secretion associated with status asthmaticus.

Despite intensive therapy, some asthmatic children will remain critically ill and at risk for intubation and mechanical ventilation. Complications related to asthma exacerbations increase with intubation and assisted ventilation; therefore, every effort should be made to relieve bronchospasm and prevent respiratory failure. Several therapies, including intravenous ß-agonists, intravenous theophylline, heliox, and intravenous magnesium sulfate have some demonstrated benefit as adjunctive therapies in severe status asthmaticus.

Intravenous Theophylline. Although several recent studies have failed to demonstrate the effectiveness of intravenous theophylline in hospitalized children receiving frequent inhaled ß-agonist and systemic glucocorticoid therapy, theophylline may still have a role in the treatment of children with severe, life-threatening asthma exacerbations. In a recent study of children with acute severe asthma (mean FEV_1 37% at baseline), intravenous theophylline resulted in a rapid and sustained increase in oxygen saturation and lung function compared with placebo. In addition, fewer patients on intravenous theophylline required intravenous albuterol; in those who did, intravenous albuterol was required for a shorter duration of time. Lastly, all study patients requiring intubation were in the placebo-treated group. This study suggests that intravenous theophylline can be an important adjunctive therapy in acute severe childhood asthma. If a child responds poorly to intensive therapy with nebulized albuterol, ipratropium, and parenteral glucocorticoids, then adding intravenous theophylline should be considered. Because theophylline use is associated with adverse effects, with overdosage resulting in dire consequences, the proper loading and maintenance doses should be used according to the child's age and weight, with serum theophylline level monitoring to ensure values within the therapeutic and nontoxic range.

Heliox. Inhaled heliox (a 70:30 helium:oxygen mixture) has been shown, in several small studies, to be effective in the treatment of acute severe asthma. Because

heliox has a density about one-third that of room air, inhalation of this gas mixture can result in decreased airways resistance and clinical improvement within 20?min, even in patients already receiving intensive inhaled ß-agonist and intravenous glucocorticoid therapy. Thus, heliox treatment early in the course of status asthmaticus may provide a period with reduced respiratory distress until ß- agonist and glucocorticoid therapy can relieve bronchoconstriction and airway narrowing. In severe cases when high-content supplemental oxygen is needed, heliox's 30% oxygen content may limit its use.

Intravenous Magnesium Sulfate. Based on its smooth muscle relaxant properties, many studies have evaluated the effect of magnesium sulfate in acute asthma, but at present it remains controversial whether magnesium is effective in acute asthma. A small controlled study in children who presented to the emergency

department with acute asthma found magnesium sulfate (25?mg/kg, maximum dose 2?g) to improve lung function and result in fewer admissions to the hospital when compared with placebo. If magnesium sulfate is to be used, blood pressure should be monitored every 10–15?min during the infusion and for up to 90?min after the infusion, because hypotension is a known adverse effect. Magnesium levels before and 30?min after the infusion should also be obtained.

Mechanical Ventilation. Rarely, a severe asthma exacerbation in children results in respiratory failure, and intubation and mechanical ventilation become necessary. Mechanical ventilation in severe asthma exacerbations requires the careful balance of enough pressure to overcome airways obstruction, while reducing hyperinflation, air trapping, and the likelihood of barotrauma (i.e., pneumothorax, pneumomediastinum). To minimize the likelihood of such complications, mechanical ventilation should be anticipated and asthmatic children at risk for the development of respiratory failure should be managed in a pediatric intensive care setting. Elective tracheal intubation with rapid-induction sedatives and paralytic agents is safer than emergency intubation. Mechanical ventilation aims to achieve adequate oxygenation while tolerating mild to moderate hypercapnia (i.e., P_{co_2} 40–60?mm?Hg) to minimize barotrauma. Volume-cycled ventilators, using short inspiratory and long expiratory times, 10–15?mL/kg tidal volume, 8–15 breaths/min, peak pressures less than 60?cm H_2O, and without positive end-expiratory pressure are starting mechanical ventilation parameters that can achieve these goals. As measures to relieve plugs of mucus in the chest, chest percussion and airways lavage are not recommended because they can induce further bronchospasm. Considering the nature of asthma exacerbations leading to respiratory failure, those of rapid or abrupt onset tend to resolve quickly (i.e., hours to 2 days); in contrast, severe asthma exacerbations that progress gradually to respiratory failure can take days to weeks for airways obstruction to improve enough to allow for cessation of mechanical ventilation. Such prolonged cases are further complicated by muscle atrophy and, when combined with corticosteroid-induced myopathy, profound muscle weakness requiring prolonged rehabilitation.

Management of severe childhood asthma exacerbations in medical centers is usually successful, even when extreme measures are required. Consequently, childhood asthma deaths rarely occur in medical centers; most asthma deaths occur at home or in community settings, before lifesaving medical care can be administered. This highlights the importance of home and community management of asthma exacerbations, emphasizing early intervention measures to keep exacerbations from becoming severe and steps to reduce asthma severity.

MANAGEMENT OF INFANTS AND YOUNG CHILDREN WITH ASTHMA.

Not every infant and small child who wheezes in the first few years of life will go on to develop asthma. Nevertheless, young children with recurrent wheezing problems can benefit from conventional reliever and controller asthma medications. As well, with wheezing exacerbations (typically triggered by viral respiratory tract infections), nebulized albuterol, and short courses of oral glucocorticoids mitigate exacerbation progression and can keep them from becoming severe.

There are three FDA-approved controller-class medications for use in young children: nebulized cromolyn, nebulized budesonide, and montelukast. Cromolyn has been widely used in infants and young children because it is available for administration by nebulization and is devoid of serious adverse effects. Unfortunately, it is not a potent medication, and administration four times daily for several weeks is necessary to achieve effective action. Nebulized budesonide is FDA approved for use in children as young as 1 yr of age. It has been extensively studied in infants and young children with recurrent wheezing and is both safe and effective. It is available for use in two concentrations (0.25?mg and 0.50?mg/vial) and can be administered once or twice daily, depending on disease severity. Montelukast is FDA approved for use in children as young as 2 yr of age (recommended dose is 4?mg once daily). Both nebulized budesonide and montelukast appear to be more effective than cromolyn. Nebulized budesonide would be indicated in young children with moderate to severe persistent asthma symptoms and in those who have failed to respond to cromolyn and montelukast. An oral medication such as montelukast that can be administered once daily offers some advantages over nebulized medications in terms of ease of use and convenience.

Treating the infant and young child with asthma with aerosol therapy presents unique challenges. The preferential nasal breathing, small airways, low tidal volume, and high respiratory rate of infants markedly increases the difficulty of drug targeting to the lung airways. Young children are incapable of reliably performing the maneuvers specified for optimal delivery of aerosol therapy delivered via an MDI or DPI. For these reasons, medication delivery devices suitable for young children are limited to those that require minimal cooperation. There are currently two types of delivery systems for inhaled medications for this age group: the nebulizer and the MDI with spacing/holding chamber and face mask. The NAEPP guidelines recommend the nebulizer for the delivery of cromolyn and high-dose short-acting ß-agonist. Inhaled glucocorticoid delivered using a MDI with spacing/holding device and face mask is considered acceptable, although perhaps not the preferred means of administering inhaled glucocorticoids to young children and infants, owing to a current paucity of published information or FDA approval.

Nebulizers have been the mainstay of aerosol treatment and remain the first choice of delivery systems for infants and young children. A major advantage of the nebulizer is the simple technique required of relaxed tidal breathing. Multiple studies

have demonstrated the effectiveness of both nebulized albuterol in acute episodes and nebulized budesonide in the treatment of recurrent wheezing in infants and young children. Disadvantages of nebulizers include expense, need for a power source, inconvenience in that treatments take about 5?min, and potential for bacterial contamination.

Studies in young children comparing the delivery of short-acting ß-agonists via MDI versus nebulizer have shown both devices to be effective in most cases, including the emergency department setting when comparable doses of medication are administered. Studies with radiolabeled albuterol given by MDI with a spacer and face mask to children younger than 5 yr old reveal less than 2% dose delivery to the lower airways. Fluticasone administered via a spacer device and face mask was clinically effective in a European study of infants and young children with recurrent wheezing.

PATIENT EDUCATION.

Specific elements in the clinical care of children with asthma, centered around education, are believed to make an important difference in the home management and adherence of families to an optimal plan of care (Box 134–10). With education, the child and family become partners in the asthma management process. In initial patient visits, a basic understanding of the pathogenesis of asthma can help asthmatic children and their parents to understand the importance of recommendations aimed at reducing airways inflammation. Good asthma control in children should be specified so that the expectations of optimal asthma management are made clear (see Box 134–5). Explaining the importance of steps to reduce airways inflammation to achieve good asthma control and addressing concerns about potential adverse effects of asthma pharmacotherapy, and especially their risks relative to their benefits, can be essential to achieve long-term adherence with asthma pharmacotherapy and environmental control measures.

All asthmatic children and their families can benefit from a written asthma management plan with two main components:

Box 134-10. Key Elements of Productive Clinic Visits for Asthma

- Specify goals of asthma management
- Explain basic facts about asthma
  - Contrast normal versus asthmatic airways
  - Link airways inflammation, “twitchiness,” and bronchoconstriction
  - Long-term-control and quick-relief medications
- Address concerns about potential adverse effects of asthma pharmacotherapy
- Teach, demonstrate, and have patient show proper technique for:
  - Inhaled medication use (spacer use with MDI)
  - Peak flow measures
- Investigate and manage factors that contribute to asthma severity
  - Environmental exposures
  - Co-morbid conditions
- Written two-part asthma management plan
  - Daily management
  - Action plan for asthma exacerbations
- Regular follow-up visits
  - Twice yearly (more often if not well controlled)
  - Monitor lung function annually

(1) a **daily management plan** describing regular asthma medication use and other measures to keep asthma under good control and (2) an **action plan for asthma exacerbations**, describing actions to take when asthma worsens, including what medications to take and when to contact the regular physician and/or obtain emergent or urgent medical care.

Regular follow-up visits can help to maintain optimal asthma control. In addition to the assessment and monitoring of disease severity, follow-up visits should evaluate adherence and concerns with asthma management recommendations, and especially the daily administration of controller medications when prescribed. Reassessment during each visit of the role of different medications in asthma management and the technique used with inhaled medication use can be insightful and lead to important teaching opportunities. Indeed, inhaled medication (and spacer) use and PEF monitoring are important skills for asthmatics to learn and improve with practice and review at each visit. Encouraging open communication of concerns about asthma management recommendations (e.g., daily controller medication use) can be insightful and improve adherence with a management plan that might not have been adequately or properly implemented.

REFERRAL FOR CONSULTATION.

NAEPP guidelines recommend referral of asthmatics to an asthma specialist, a board-certified allergist, or pulmonologist for consultation. Asthma specialists can typically provide lung function testing, allergen sensitization assessment and testing, detailed evaluation for asthma masqueraders (e.g., flexible rhinolaryngoscopy or bronchoscopy), bronchoprovocation challenges, environmental assessment and modification recommendations, extensive patient and parent education, and management support of complex or severe asthmatics. Asthmatics with upper airways conditions may require referral to an otolaryngologist. Asthmatics with psychosocial risk factors for asthma morbidity or mortality may benefit from referral to a mental health professional.

Prevention.

Currently, asthma prevention strategies are in their infancy. With recent evidence that chronic airways inflammation may result in pathologic remodeling changes, early intervention with anti-inflammatory medications in young children with recurrent wheezing and persistent asthma risk factors may halt disease progression. Investigations into the environmental and lifestyle factors responsible for the lower prevalence of childhood asthma in rural areas and farming communities suggest that early immune modulatory intervention might prevent asthma development. A “hygiene hypothesis” purports that microbial exposures in early life might drive early immune development away from allergen sensitization and allergic inflammation. Accordingly, early life microbial exposures have been associated with a lower likelihood of allergen sensitization and atopic dermatitis in infants and a lower likelihood of asthma and bronchial hyperresponsiveness in later childhood. If these microbial exposures truly have an asthma-protective effect, then these findings may foster new strategies for asthma prevention.

Current evidence also suggests that several other nonpharmacotherapeutic measures with numerous positive health attributes—avoidance of environmental tobacco smoke (beginning prenatally), prolonged breast-feeding (greater than 4 mo), an active lifestyle, and a healthy diet—might reduce the likelihood of asthma development. Immunizations are currently not considered to increase the likelihood of developing asthma; therefore, all standard childhood immunizations are recommended for asthmatic children, including varicella and annual influenza vaccines.

Chapter 135 - Atopic Dermatitis (Atopic Eczema)

Donald Y. M. Leung

Atopic dermatitis (AD) is a highly pruritic skin disease that affects more than 10% of children. It is frequently associated with elevated serum IgE levels, and nearly 80% of patients with AD develop allergic rhinitis and/or asthma.

Pathogenesis.

Complex interactions between genetic, environmental, and immunologic factors contribute to the pathogenesis of AD. Current therapies in AD have evolved from an understanding of the pathobiology of this disease.

SYSTEMIC IMMUNE RESPONSE.

Most patients with AD have peripheral blood eosinophilia and increased serum IgE levels. Peripheral blood T cells from AD patients produce decreased amounts of interferon-gamma (IFN-?), an inhibitor of T helper type 2 (Th2) cell function. IFN-? generation ex vivo is inversely correlated with serum IgE concentrations in AD. An increased frequency of allergen-specific T cells producing increased interleukin (IL)-4, IL-5, and IL-13 in the peripheral blood of patients with AD contributes to the eosinophilia and increased IgE levels in AD.

SKIN IMMUNOPATHOLOGY.

Clinically *unaffected* skin of AD patients is not normal but reveals mild epidermal hyperplasia and a sparse perivascular T-cell infiltrate. Acute skin lesions are characterized by **spongiosis,** or marked intercellular edema, of the epidermis. The dendritic antigen-presenting cells (APCs) in the skin, Langerhans cells (LCs), in lesional and, to a lesser extent, nonlesional skin of AD exhibit surface-bound IgE

molecules. IgE-bearing LCs appear to play an important role in cutaneous allergen presentation to Th2 cells (see Chapter 130). In the acute lesion, there is a marked perivenular T-cell infiltrate with occasional monocyte-macrophages. Mast cells are found in normal numbers in different stages of degranulation.

Chronic lichenified lesions are characterized by a hyperplastic epidermis with elongation of the rete ridges, hyperkeratosis, and minimal spongiosis. There are predominantly IgE-bearing LCs in the epidermis and macrophages in the dermal mononuclear cell infiltrate. The numbers of mast cells and of eosinophils are increased. Eosinophils are thought to contribute to allergic inflammation by the secretion of cytokines and mediators that augment allergic inflammation and induce tissue injury in AD through the production of reactive oxygen intermediates and release of toxic granule proteins.

SKIN IMMUNE RESPONSE.

As compared with the skin of normal control subjects, unaffected skin and acute skin lesions of AD have an increased number of cells expressing IL-4 and IL-13. However, acute AD does not contain significant numbers of cells that express IFN-? or IL-12. Chronic AD skin lesions have significantly fewer cells that express IL-4 and IL-13 but increased numbers of cells that express IL-5, granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-12, and IFN-? than acute AD. Thus, acute T-cell infiltration in AD is associated with a predominance of IL-4 and IL-13 expression whereas maintenance of chronic inflammation is associated with increased IL-5, GM-CSF, IL-12, and IFN-? expression and is accompanied by the infiltration of eosinophils and macrophages. The increased expression of IL-12 in chronic AD skin lesions is of interest because cytokine plays a key role in Th1 cell development and its expression in eosinophils and/or macrophages may initiate the switch to Th1 or Th0 cell development in chronic AD.

GENETICS.

AD is familially transmitted with a strong maternal influence. Genetic approaches have identified candidate genes, suggesting that AD has a common genetic basis with other allergic diseases. There has been particular interest in the role of chromosome 5q31-33 because it contains a clustered family of cytokine genes, namely, IL-3, IL-4, IL-5, IL-13, and GM-CSF, which are expressed by Th2 cells. A case control comparison has suggested a genotypic association between the T allele of the -590C/T polymorphism of the IL-4 gene promoter region with AD. Because the T allele is associated with increased IL-4 gene promoter activity compared with the C allele, this suggests that genetic differences in transcriptional activity of the IL-4 gene influence AD predisposition. In addition, an association of AD with a gain-of-function mutation in the a subunit of the IL-4 receptor has been reported. A functional mutation in the promoter region of the C-C chemokine RANTES and an IL-13 coding region variant also occurs in AD.

Two genome-wide linkage studies have also identified susceptibility loci for AD. Linkage for AD has been found on chromosome 3q21, a region that encodes the co-stimulatory molecules CD80 and CD86 involved in T-cell activation as well as chromosome 1q21 and 17q25 identifying loci, which closely coincide with regions linked to psoriasis. Thus, AD is also influenced by genes that modulate skin responses independent of allergic mechanisms.

Clinical Manifestations.

AD typically begins during infancy. Approximately 50% of patients develop this illness by the first year of life, and an additional 30% are diagnosed between 1–5 yr of age. Intense pruritus and cutaneous reactivity are cardinal features of AD. Pruritus is usually worse at night. Its consequences are scratching that contributes to the induction of eczematous skin lesions. Foods, inhalant allergens, bacterial infection, reduced humidity, excessive sweating, and irritants (e.g., wool, acrylic, soaps, and detergents) can exacerbate pruritus and scratching.

SKIN REACTION PATTERNS.

Acute AD skin lesions are intensely pruritic, erythematous papules associated with excoriation and serous exudate. Subacute dermatitis is characterized by erythematous, excoriated, scaling papules. Chronic AD is characterized by lichenification (thickening of the skin with accentuated surface markings) and fibrotic papules (prurigo nodularis). In chronic AD, all three stages of skin reactions can coexist in the same individual. Most AD patients usually also have dry lackluster skin.

The distribution and skin reaction pattern varies with the patient's age and disease activity. During infancy, the AD is generally more acute and involves the face, scalp, and the extensor surfaces of the extremities. The diaper area is usually spared. In older children and in those who have long-standing skin disease, the patient develops chronic AD with lichenification and localization of the rash to the flexural folds of the extremities. AD often goes into remission as the patient grows older, leaving an adolescent or adult with skin that is prone to itching and inflammation when exposed to exogenous irritants.

Diagnosis.

Of the major features (Box 135–1), pruritus and chronic remitting eczematous dermatitis with typical morphology and distribution are essential for the diagnosis of AD. Other associated features, including a family history of asthma, hay fever, elevated IgE, and immediate skin test reactivity, are variable.

DIFFERENTIAL DIAGNOSIS.

A number of inflammatory skin diseases, immunodeficiencies, skin malignancies, genetic disorders, infectious diseases, and infestations share symptoms and signs with AD and should be considered and excluded before a diagnosis of AD is established. Infants presenting in the 1st year of life with failure to thrive, diarrhea, generalized scaling erythematous rash, and recurrent cutaneous and/or systemic infections should be evaluated for severe combined immunodeficiency syndrome (see Chapter 116.1). In addition, histiocytosis X (see Chapter 499) should be ruled out in any infant with AD and failure to thrive. Wiskott-Aldrich syndrome (see Chapter 116.2) is an X-linked recessive disorder, associated with thrombocytopenia, immune defects, and recurrent severe bacterial infections, characterized by a rash almost indistinguishable from AD. The hyper-IgE syndrome (see Chapter 116.2) is characterized by markedly elevated serum IgE levels, recurrent deep-seated bacterial infections, chronic dermatitis, and recalcitrant dermatophytosis.

Adolescents who present with an eczematous dermatitis with no history of childhood eczema, respiratory allergy, or atopic family history may have allergic contact dermatitis. A contact

Box 135-1. Clinical Features of Atopic Dermatitis

MAJOR FEATURES

- Pruritus
- Facial and extensor eczema in infants and children
- Flexural eczema in adolescents
- Chronic or relapsing dermatitis
- Personal or family history of atopic disease

ASSOCIATED FEATURES

- Xerosis
- Cutaneous infections
- Nonspecific dermatitis of the hands or feet
- Ichthyosis, palmar hyperlinearity, keratosis pilaris
- Nipple eczema
- White dermatographism and delayed blanch response
- Anterior subcapsular cataracts, keratoconus
- Elevated serum IgE levels
- Positive immediate-type allergy skin tests

Elevated serum IgE levels

Positive immediate-type allergy skin tests

Early age at onset

Dennie lines (Dennie-Morgan infraorbital folds)

Facial erythema or pallor

Course influenced by environmental and/or emotional factors

allergen should be considered in any patient whose AD does not respond to appropriate therapy, because chemicals such as parabens and lanolin are commonly used therapeutic topical agents. Topical glucocorticoid contact allergy has been reported increasingly in patients with chronic dermatitis on topical corticosteroid therapy. Eczematous dermatitis has also been reported with HIV infection as well as with a variety of infestations such as scabies. Other conditions that can be confused with AD include psoriasis, ichthyoses, and seborrheic dermatitis.

Treatment.

The treatment of AD requires a systematic, multifaceted approach that incorporates skin hydration, topical therapy, identification and elimination of flare factors, and, if necessary, systemic therapy.

TOPICAL THERAPY.

Although it is imperative to identify and eliminate the causative factors, topical therapy, especially cutaneous hydration, is usually indicated once symptoms of AD are present.

Cutaneous Hydration. Patients with AD have decreased skin barrier function contributing to the development of **xerosis,** or dry skin, especially during the winter. Lukewarm soaking baths for at least 20?min followed by the application of an occlusive emollient to retain moisture gives patients symptomatic relief. Hydrophilic ointments can be obtained in varying degrees of viscosity according to the patient's preference. Occlusive ointments are sometimes not well tolerated because of interference with the function of the eccrine sweat ducts and may induce the development of folliculitis. In these patients, less-occlusive agents should be used.

Hydration, by baths or wet dressings, promotes transepidermal penetration of topical glucocorticoids. Dressings may also serve as an effective barrier against persistent scratching, which promotes more rapid healing of excoriated lesions. Wet dressings are recommended for use on severely affected or chronically involved areas of dermatitis refractory to skin care. However, they have the potential to promote drying and fissuring of the skin if not followed by topical emollient use. Wet dressing therapy can be complicated by maceration and secondary infection and should be closely monitored by a physician.

Topical Glucocorticoid Treatment. Topical glucocorticoids are frequently the cornerstone of anti-inflammatory treatment for AD. Patients should be carefully instructed on their use of topical glucocorticoids in order to avoid potential adverse effects. There are seven classes of topical glucocorticoids, ranked according to their potency based on vasoconstrictor assays. Because of their potential adverse effects, the ultra-high-potency glucocorticoids should not be used on the face or intertriginous areas and only for very short periods of time on the trunk and extremities. The goal is to use emollients to enhance skin hydration and low-potency glucocorticoids for maintenance therapy. Mid-potency glucocorticoids can be used for longer periods of time to treat chronic AD involving the trunk and extremities.

Compared with creams, ointments have a greater potential to occlude the epidermis, resulting in enhanced systemic absorption. Adverse effects from topical glucocorticoids can be divided into local adverse effects and systemic adverse effects resulting from suppression of the hypothalamic-pituitary-adrenal axis. Local adverse effects include the development of striae and skin atrophy. Systemic adverse effects are related to the potency of the topical glucocorticoid, the site of application, the occlusiveness of the preparation, the percentage of the body surface area covered, and the length of use. The potential for potent topical glucocorticoid to cause adrenal suppression is greatest in infants and young children with severe AD requiring intensive therapy.

Topical Immunomodulators. Topically applied tacrolimus, a calcineurin inhibitor that acts by binding to FK binding protein, has been successfully used in the treatment of AD. Tacrolimus inhibits the activation of a number of key cells involved in AD, including T cells, Langerhans cells, mast cells, and keratinocytes. AD patients receiving this form of therapy can have markedly diminished pruritus and reduced skin inflammation within several days of initiating therapy. Multicenter, blinded, vehicle-controlled trials have shown tacrolimus ointment to be both safe and effective in children with AD. Local burning sensation has been the only common adverse event. Long-term open-label studies with tacrolimus ointment have demonstrated sustained efficacy and no significant adverse effects. Indeed, *S. aureus* colonization decreases during long-term therapy with tacrolimus ointment. In addition, unlike topical corticosteroids, tacrolimus ointment does not cause cutaneous atrophy and has been used safely for facial and eyelid eczema. Tacrolimus ointment 0.03% has been approved by the U.S. Food and Drug Administration for short-term and intermittent long-term use in AD for children 2–15 yr of age, and 0.03% as well as 0.1% has been approved for patients older than age 16 yr.

Ascomycin compounds, which act by binding to macrophilin 12 to interfere with calcineurin action, have been developed in topical and oral forms, which appear to have preferential drug distribution to the skin. Like tacrolimus, they inhibit Th1 and Th2 cytokine production and have been found to be effective in the treatment of AD.

Tar Preparations. Coal tar preparations have antipruritic and anti-inflammatory effects on the skin. The anti-inflammatory properties of tars, however, are usually not as pronounced as those of topical glucocorticoids or macrolide immunomodulators. Tar preparations are useful in reducing the potency of topical glucocorticoids

required in chronic maintenance therapy of AD. Tar shampoos can be particularly beneficial for scalp dermatitis. Adverse effects associated with tar preparations can include skin irritation, folliculitis, and photosensitivity.

Phototherapy. Broad-band ultraviolet B, broad-band ultraviolet A, narrow-band ultraviolet B (311?nm), UVA-1 (340–400?nm), and combined UVA/B phototherapy can be useful adjuncts in the treatment of AD. Investigation of the mechanisms responsible for their therapeutic effectiveness indicate that epidermal Langerhans cells and eosinophils may be targets of ultraviolet A phototherapy with (PUVA) and without psoralen, whereas UVB exerts immunosuppressive effects through blocking of function of antigen-presenting Langerhans cells and altered keratinocyte cytokine production. Photochemotherapy with PUVA may be indicated in patients with severe, widespread AD. Short-term adverse effects with phototherapy include erythema, skin pain, pruritus, and pigmentation. Long- term adverse effects include predisposition to cutaneous malignancies.

IDENTIFICATION AND ELIMINATION OF TRIGGERING FACTORS.

It is essential to identify and eliminate triggering factors, both during the period of acute symptoms and on an ongoing basis after symptoms have abated, in an attempt to prevent recurrences.

Irritants. Patients with AD have a low threshold for response to irritants that can trigger their itch-scratch cycle. These include soaps or detergents, contact with chemicals, smoke, abrasive clothing, and exposure to extremes of temperature and humidity. When soaps are used, they should have minimal defatting activity and a neutral pH. New clothing should be laundered before wearing to decrease levels of formaldehyde and other added chemicals. Residual laundry detergent in clothing may be irritating. Using a liquid rather than powder detergent and adding a second rinse cycle will facilitate removal of the detergent.

Every attempt should be made to allow children to be as normally active as possible. Certain sports such as swimming may be better tolerated than other sports involving intense perspiration, physical contact, or heavy clothing and equipment, but chlorine should be rinsed off immediately after swimming and

the skin lubricated. Although ultraviolet light may be beneficial to some patients with AD, sunscreens should be used to avoid sunburn.

Foods. Well-controlled studies have demonstrated that food allergens induce rashes in children with AD (see Chapter 142). Based on double-blind, placebo-controlled food challenges, approximately 40% of infants and young children with moderate to severe AD have food allergy. Food allergies in AD patients may induce eczematous dermatitis in some patients, whereas in others urticarial reactions, contact urticaria, wheezing, or nasal congestion is elicited. Increased severity of AD symptoms and younger age of patients correlate directly with the presence of food allergy. Removal of food allergens from the patient's diet can lead to significant clinical improvement but requires a great deal of education because most of the common allergens (e.g., egg, milk, wheat, soy, and peanut) contaminate many foods and are therefore difficult to avoid.

Potential allergens can be identified by taking a careful history and carrying out selective skin prick tests or in vitro blood testing. Negative skin tests or serum tests for allergen-specific IgE have a high predictive value for excluding suspected allergens. Positive skin or in vitro blood tests to foods often do not correlate with clinical symptoms and should be confirmed with controlled food challenges and elimination diets. Extensive elimination diets, which in some cases can be nutritionally deficient, are rarely required because even with multiple positive skin tests the majority of patients will react to fewer than three foods on controlled challenge.

Aeroallergens. In older children, exacerbation of AD can occur after intranasal or epicutaneous exposure to aeroallergens such as fungi, animal dander, grass, or ragweed pollen. In such patients, avoidance of aeroallergens, particularly dust mites, can result in clinical improvement of AD. In dust mite–allergic patients, avoidance measures include use of dust mite–proof encasings on pillows, mattresses, and box springs; washing bedding in hot water weekly; removal of bedroom carpeting; and decreasing indoor humidity levels with air conditioning.

Infections. Patients with AD have an increased tendency to develop bacterial, viral, and fungal skin infections. Antistaphylococcal antibiotics are very helpful in the treatment of patients who are heavily colonized or infected with *S. aureus*. Erythromycin and the newer macrolide antibiotics azithromycin and clarithromycin are usually beneficial for patients who are not colonized with a resistant *S. aureus* strain. However, for macrolide- resistant *S. aureus*, a penicillinase-resistant penicillin (dicloxacillin) or 1st-generation cephalosporin (cephalexin) may be preferred. Topical mupirocin is useful in the treatment of impetiginized lesions; however, in patients with AD and extensive superinfection, a course of systemic antibiotics is most practical. Recent studies demonstrating that IL-4–mediated skin inflammation contributes to skin colonization with *S. aureus* indicate the importance of combining effective anti-inflammatory therapy with antibiotics in the treatment of patients with moderate to severe AD to avoid the need for repeated courses of antibiotics, which can lead to the emergence of antibiotic-resistant strains of *S. aureus*.

Herpes simplex virus (HSV) can provoke recurrent dermatitis and may be misdiagnosed as *S. aureus* infection. The presence of erosive, punched-out erosions, vesicles, and/or infected skin lesions that fail to respond to oral antibiotics should suggest HSV infection. This can be diagnosed by a Giemsa-stained Tzanck smear of cells scraped from the vesicle base or by viral culture. For suspected infection from HSV, topical glucocorticoids are best temporarily discontinued. Antiviral treatment for cutaneous HSV infections is of critical importance in the patient with widespread AD because life-threatening dissemination has been reported.

Dermatophyte infections can contribute to exacerbation of AD disease activity. Patients with dermatophyte infection or IgE antibodies to *Malassezia furfur* (formerly known as *Pityrosporum ovale*) may benefit from a trial of topical or systemic antifungal therapy.

SYSTEMIC THERAPY.

Systemic therapies for AD include antihistamines, glucocorticoids, cyclosporine, and interferons, and are used for more severe cases.

Antihistamines. Systemic antihistamines act primarily by blocking the H_1 -receptors in the dermis, thereby reducing histamine-induced pruritus. However, histamine is only one of many mediators that can induce pruritus of the skin and, therefore, patients may derive minimal benefit from antihistaminic therapy. Because pruritus is usually worse at night, the sedating antihistamines (e.g., hydroxyzine or diphenhydramine) may offer an advantage with their soporific adverse effects when used at bedtime. Doxepin hydrochloride has both tricyclic antidepressant and H_1 - and H_2 -receptor blocking effects. If nocturnal pruritus remains severe, short-term use of a sedative to allow adequate rest may be appropriate. Studies of newer nonsedating antihistamines have shown variable results in the effectiveness of controlling pruritus in AD, although they may be useful in the small subset of AD patients with concomitant urticaria.

Systemic Glucocorticoids. The use of systemic glucocorticoids is rarely indicated in the treatment of chronic AD. The dramatic clinical improvement that may occur with systemic glucocorticoids is frequently associated with a severe rebound flare of AD after discontinuation. Short courses of oral glucocorticoids may be appropriate for an acute exacerbation of AD, whereas other treatment measures are being instituted. If a short course of oral glucocorticoids is given, it is important to taper the dosage and begin intensified skin care, particularly with topical glucocorticoids and frequent bathing followed by application of emollients, to prevent rebound flaring of AD.

Cyclosporine. Cyclosporine is a potent immunosuppressive drug that acts primarily on T cells by suppressing cytokine transcription. The drug binds to an intracellular protein, cyclophilin, and this complex in turn inhibits calcineurin, a molecule required for initiation of cytokine gene transcription. Multiple studies have demonstrated that children with severe AD, refractory to conventional treatment, can benefit from short-term cyclosporine treatment. A dose of 5?mg/kg/24?hr has been utilized with success in short-term and long-term (1 yr) use. Renal impairment and hypertension are specific adverse effects of concern with cyclosporine use.

Interferons. Interferon-gamma (IFN-?) is known to suppress IgE responses and downregulate TH2 cell proliferation and function. Several studies of patients with AD, including a multicenter, double-blinded, placebo-controlled trial, have demonstrated that treatment with recombinant IFN-? results in clinical improvement. Reduction in clinical severity of AD correlated with the ability of IFN-? to decrease total circulating eosinophil counts. Influenza-like symptoms are commonly observed adverse effects early in the treatment course.

Complications.

AD is associated with recurrent viral skin infections. The most serious viral infection is **Kaposi varicelliform eruption** or **eczema herpeticum,** which is caused by HSV and affects patients of all ages. After exposure of affected skin to the virus and after an incubation period of 5–12 days, multiple, itchy, vesiculopustular lesions erupt in a disseminated pattern; the vesicular lesions are umbilicated, tend to crop, and often become hemorrhagic and crusted. Patients can also suffer from frequent infection with viruses leading to warts and molluscum contagiosum. Persons with AD are susceptible to **eczema vaccinatum,** a widespread severe viral skin infection caused by variola virus (smallpox), which is similar in appearance to eczema herpeticum and historically follows smallpox vaccination or exposure to individuals vaccinated with smallpox. This form of infection is a potential occurrence in the event of a bioterrorism attack with smallpox (see Chapter 706).

Patients with AD have an increased prevalence of *Trichophyton rubrum* fungal infections compared with nonatopic controls. There has been particular interest in the role of *M. furfur* in AD because it is a lipophilic yeast commonly present in the seborrheic areas of the skin. IgE antibodies against *M. furfur* have been found in patients with head and neck dermatitis. In such patients, a reduction of AD skin severity has been observed after treatment with antifungal agents.

Staphylococcus aureus is found on over 90% of AD skin lesions. Honey-colored crusting, folliculitis, impetigo, and pyoderma are indicators of *S. aureus* skin infection that requires antibiotic therapy. Regional lymphadenopathy is common in such patients. The importance of *S. aureus* in AD is supported by the observation that patients with severe AD, even those without overt infection, can show clinical response to combined treatment with antistaphylococcal antibiotics and topical glucocorticoids.

Patients with extensive skin involvement may develop exfoliative dermatitis. This is associated with generalized redness, scaling, weeping, crusting, systemic toxicity, lymphadenopathy, and fever. It is usually caused by superinfection (e.g., with toxin-producing *S. aureus* or HSV infection) or inappropriate therapy. In some cases, the withdrawal of systemic glucocorticoids used to control severe AD may be a precipitating factor for exfoliative erythroderma.

Eyelid dermatitis and chronic blepharitis may result in visual impairment from corneal scarring. Atopic keratoconjunctivitis is usually bilateral and can have disabling symptoms that include itching, burning, tearing, and copious mucoid discharge. Vernal conjunctivitis is associated with papillary hypertrophy or cobblestoning of the upper eyelid conjunctiva. It usually occurs in younger patients and has a marked seasonal incidence with exacerbation in the spring. Keratoconus is a conical deformity of the cornea believed to result from chronic rubbing of the eyes in patients with AD. Cataracts may be a primary manifestation of AD or from the extensive use of systemic and topical glucocorticoids, particularly around the eyes.

Prognosis.

AD generally tends to be more severe and persistent in young children. Periods of remission appear more frequently as the patient grows older. Spontaneous resolution of AD has been reported to occur after age 5 yr in 40–60% of patients

affected during infancy, particularly if their disease is mild. Although earlier studies suggested that approximately 84% of children outgrow their AD by adolescence, more recent studies have reported that AD disappears in approximately 20% of children followed from infancy until adolescence but it had become less severe in 65%. In addition, more than half of those adolescents treated for mild dermatitis may experience a relapse of disease as adults, frequently presenting with hand dermatitis, especially if daily activities require repeated hand wetting. The following predictive factors correlate with a poor prognosis for AD: widespread AD in childhood, concomitant allergic rhinitis and asthma, family history of AD in parents or siblings, early age at onset of AD, being an only child, and very high serum IgE levels.

Prevention.

Identification and elimination of triggering factors as part of treatment of AD is also the mainstay of prevention of recurrences.

Chapter 136 - Urticaria and Angioedema (Hives)

Donald Y. M. Leung

Urticaria and angioedema affects 20% of the population at some point during their life. Urticaria and angioedema is usually classified according to its duration. Skin lesions that last less than 6 wk duration are considered acute, and episodes that persist for more than 6 wk are designated chronic. This distinction is important because the causes and mechanisms of urticaria formation are different in each instance as are the therapeutic approaches.

Etiology and Pathogenesis.

Acute urticaria and angioedema is often caused by an allergic (IgE-mediated) reaction (Table 136–1). This form of urticaria is a self-limited process that occurs when an allergen activates mast cells in the skin, which leads to mast cell degranulation and secretion of histamine, leukotrienes, enzymes such as tryptase and chymase, cytokines, and chemokines. Systemically absorbed allergens that can result in generalized urticaria include foods, drugs (particularly antibiotics), and stinging insect venoms. If an allergen can penetrate the skin locally, hives can develop at the site of exposure. Contact urticaria, for example, might occur after exposure to latex gloves if sufficient latex penetrates through the skin. Acute urticaria can also result from non–IgE-mediated stimulation of mast cells, including that from radiocontrast agents, viral agents including hepatitis B and Epstein-Barr virus, opiates, and nonsteroidal anti-inflammatory agents.

Chronic urticaria and angioedema is diagnosed when hives and swelling are present for more than 6 wk, but symptoms commonly exceed 12 wk. Once it has been determined that a protracted episode of urticaria is not physical urticaria or recurrent acute urticaria with repeated exposures to an agent, the diagnosis of chronic urticaria and angioedema can be established.

Urticaria can also be classified according to the rate in which hive formation occurs and the length of time it is evident. One

TABLE 136-1 -- **Diagnostic Testing for Urticaria/Angioedema**

Potential Condition	Procedure
Food and drug reactions	Elimination of offending agent, skin testing, and challenge with suspected foods
Inhalant allergens	Skin tests, radioallergosorbent test
Infections	Appropriate cultures or serology
Collagen vascular diseases and cutaneous vasculitis	Skin biopsy, CH_{50} , C4, C3, factor B, immunofluorescence of tissue, antinuclear antibodies, cryoglobulins
Malignancy with angioedema	CH_{50} , C1q, C4, C1 INH determinations
Cold urticaria	Ice cube test
Solar urticaria	Exposure to defined wavelengths of light, red cell protoporphyrin, fecal protoporphyrin, and coproporphyrin
Dermatographism	Stroking with narrow object (e.g., tongue blade, fingernail)
Pressure urticaria	Application of pressure for defined time and intensity
Vibratory angioedema	Vibration for 4 min
Aquagenic urticaria	Challenge with tap water at various temperatures
Urticaria pigmentosa	Skin biopsy, test for dermographism
Hereditary angioedema	C4, C2, CH_{50} , C1 INH by protein and function
Familial cold urticaria	Challenge by cold exposure, measurement of temperature, white blood cell count, erythrocyte sedimentation rate, and skin biopsy
C3b inactivator deficiency	C3, factor B, C3b inactivator determinations
Chronic idiopathic urticaria	Skin biopsy, immunofluorescence (negative result), autologous skin test

form of urticaria has lesions that last 1–2?hr and is typically encountered with physically induced hives with an inciting stimulus that is present only briefly; there is prompt mast cell degranulation, and biopsy of such lesions reveals little or no cellular infiltrate. The second form or urticaria has a prominent cellular infiltrate, and individual lesions can last as long as 36?hr. This can be found with food or drug reactions, delayed pressure urticaria, and chronic urticaria. Serum sickness reactions can be seen as a manifestation of drug reactions and on biopsy reveals a small-vessel cutaneous vasculitis. Urticaria in association with systemic lupus erythematosus or other vasculitides appears similar.

Atypical aspects of the gross appearance of the hives should heighten concern that the urticaria or angioedema may be the manifestation of a more systemic disease process. Lesions that do not blanch or are associated with bleeding into the skin (i.e., purpura) suggest urticarial vasculitis.

PHYSICAL URTICARIAS.

Physically induced urticaria and/ or angioedema share the common property of being induced by environmental factors, such as a change in temperature or by direct stimulation of the skin with pressure, stroking, vibration, or light (see Table 136–1).

Cold-Dependent Disorders. Cold urticaria is characterized by the rapid onset of pruritus, erythema, and urticaria/ angioedema after exposure to a cold stimulus. The location of the swelling is confined to those parts of the body that have been exposed. However, total-body exposure such as occurs with swimming can cause massive release of vasoactive mediators, resulting in hypotension and even death if not promptly treated. The diagnosis is confirmed by challenge testing for an isomorphic cold reaction with an ice cube placed on the patient's skin for 10–15?min. Patients with cold urticaria will have a positive reaction on rewarming of the chilled skin. Cold urticaria can be associated with the presence of **cryoproteins** such as

cold agglutinins, cryoglobulins, cryofibrinogen, and the Donath-Landsteiner antibody seen in secondary syphilis (paroxysmal cold hemoglobinuria). In patients with associated cryoglobulins, the isolated proteins appear to transfer cold sensitivity and activate the complement cascade on in vitro incubation with normal plasma. The term **idiopathic cold urticaria** generally applies to patients without abnormal circulating plasma proteins such as cryoglobulins. However, there is evidence that in some patients, chilling initiates an immune reaction mediated by an abnormal IgE bound to mast cells, which, on warming, leads to mediator release into the circulation. Cold urticaria has also been reported after viral infections.

Cholinergic Urticaria. This form of urticaria is characterized by the onset of small punctate wheals surrounded by a prominent erythematous flare associated with exercise, hot showers, and sweating. When the patient cools down, the rash usually subsides in 30–60?min. Also occasionally seen are symptoms of more generalized cholinergic stimulation such as lacrimation, wheezing, salivation, and syncope. These symptoms are mediated by cholinergic nerve fibers that innervate the musculature via parasympathetic neurons and innervate the sweat glands by cholinergic fibers that travel with the sympathetic nerves. Studies of mediator release during attacks of cholinergic urticaria have demonstrated that elevated plasma histamine levels parallel the onset of urticaria triggered by changes in body temperature.

Dermatographism. The ability to write on skin, termed **dermatographism**, can occur as an isolated disorder or accompany chronic urticaria or other physical urticarias, such as cholinergic and cold urticaria. It can be diagnosed by observing the skin after stroking it with a tongue depressor or fingernail. In such patients, a linear response occurs secondary to reflex vasoconstriction, followed by pruritus, erythema, and a linear wheal. In approximately 50% of cases, passive-transfer studies have demonstrated an IgE-dependent mechanism.

Pressure-Induced Urticaria and Angioedema. Pressure-induced urticaria differs from most types of urticaria or angioedema in that symptoms typically occur 4–6?hr after pressure has been applied. The disorder is clinically heterogeneous in that some patients may complain of swelling secondary to pressure with normal-appearing skin (i.e., no urticaria), so that the term **angioedema** is more appropriate. Others are predominantly urticarial and may or may not be associated with significant swelling. When urticaria is present, an infiltrative skin lesion is seen characterized by a perivascular mononuclear cell infiltrate and dermal edema similar to that seen with chronic idiopathic urticaria. Symptoms occur about tight clothing; foot swelling is common after walking; and buttock swelling may be prominent after sitting for a few hours. This condition generally coexists with chronic idiopathic urticaria. The diagnosis is confirmed by challenge testing by pressure applied perpendicular to the skin.

Solar Urticaria. Solar urticaria is a rare disorder in which urticaria develops within 1–3?min of sun exposure. Typically, pruritus occurs first, in about 30?sec, followed by edema confined to the light-exposed area and surrounded by a prominent erythematous zone caused by an axon reflex. The lesions usually disappear within 1–3?hr after sun exposure is avoided. When large areas of the body are exposed, systemic symptoms may occur, including hypotension and wheezing. Solar urticaria has been classified into six types, depending on (1) the wavelength of light that induces skin lesions and (2) the ability or inability to passively transfer the disorder with serum IgE. The rare inborn error of metabolism erythropoietic protoporphyria can be confused with solar urticaria because of the development of itching and burning of exposed skin immediately after sun exposure. In erythropoietic protoporphyria, fluorescence of UV-irradiated red blood cells can be demonstrated.

Aquagenic Urticaria. Patients with aquagenic urticaria develop small wheals after contact with water, regardless of its temperature, and are therefore distinguishable from patients with cold urticaria or cholinergic urticaria. Direct application of a compress of water to the skin is used to test for its presence. The diagnosis should be reserved for those rare cases that test positively for contact with water but negatively for all other forms of physical urticaria.

CHRONIC IDIOPATHIC URTICARIA AND ANGIOEDEMA.

This is a common disorder of unknown origin that is often associated with normal routine laboratory studies, including normal white blood cell count and erythrocyte sedimentation rate (ESR), with no evidence of systemic disease. Chronic urticaria does not appear to be an allergic reaction. It differs from allergen-induced skin reactions or from physically induced urticaria in that histologic studies reveal a cellular infiltrate predominantly about small venules. Skin examination reveals infiltrative hives with palpably elevated borders, sometimes varying greatly in size and/or shape but generally being rounded.

Biopsy of the typical lesion consists of a non-necrotizing perivascular mononuclear cell infiltrate. However, many types of histopathologic processes can occur in the skin and manifest as urticaria. For example, patients with hypocomplementemia and cutaneous vasculitis can have urticaria or angioedema and biopsy of patients with urticaria, arthralgias, myalgias, and an elevated ESR as manifestations of necrotizing venulitis can reveal fibrinoid necrosis with a predominant neutrophilic infiltrate. Yet the urticarial lesions may be clinically indistinguishable from those seen in the more typical, nonvasculitis cases.

There is an increased association of chronic urticaria with Hashimoto thyroiditis. Such patients generally have antibodies to thyroglobulin or a microsomal-derived antigen (peroxidate) even if they are euthyroid. The incidence of abnormal thyroid function (either increased or decreased thyroxine [T_4] and/ or increased or decreased thyroid stimulating hormone) is

---

approximately 20%. Although some patients show clinical reduction of their urticaria on thyroid replacement therapy, many do not. Therefore, some investigators believe that these are associated, parallel, autoimmune events.

Thirty-five to 40 per cent of patients with chronic urticaria have a positive **autologous skin test:** if serum from the patient is intradermally injected into their skin, a significant wheal and flare reaction is observed. Such patients frequently have an IgG antibody directed to the a subunit of the IgE receptor that could cross link the IgE receptor (a subunit) and degranulate mast cells and basophils. An additional

5–10% of chronic urticaria patients have anti-IgE antibodies rather than anti-IgE receptor antibody. Cutaneous mast cell activation by IgG autoantibodies, however, generally requires the classical complement pathway with involvement of C3a and C5a, which are chemoattractants for inflammatory cells and can activate mast cell degranulation.

Diagnosis.

Allergy skin testing can be helpful in sorting out causes of acute urticaria, especially when supported by historical evidence. Drugs and foods are the most common causes of acute urticaria. Dermatographism is frequent in patients with urticaria and can complicate allergy skin testing by causing false-positive reactions. In the absence of any clue suggesting an ingestant cause, elimination diets generally are not useful. The diagnosis is clinical and requires that the physician be aware of the various forms of urticaria.

An exogenous cause of chronic urticaria is rarely identified, reflecting its autoimmune nature. The differential diagnosis of chronic urticaria includes cutaneous or systemic mastocytosis, complement-mediated disorders, malignancies, mixed connective tissue diseases, and cutaneous blistering disorders (e.g., bullous pemphigoid). Only a few screening laboratory tests are useful, including a complete blood cell count with differential, ESR, urinalysis, thyroid autoantibodies, and liver function tests. Further studies are warranted if the patient has fever, arthralgias, or elevated ESR because there is an increased possibility of systemic illness such as malignancy or vasculitis. In such situations, a chest radiograph, skin biopsy, and complement studies may be done (see Table 136–1). C3b inactivator (factor I) deficiency has also been found in some cases of urticaria. Hereditary angioedema, a potentially life-threatening form of angioedema associated with deficient C1 inhibitor activity, is the most important familial form of angioedema (see Chapter 124.3). In patients with eosinophilia, stools for ova and parasites should be obtained because infection with helminthic parasites have been associated with urticaria. A syndrome of episodic angioedema/ urticaria and fever with associated eosinophilia has been described in both adults and children. In contrast to other hypereosinophilic syndromes, this entity has a benign course.

Skin biopsy for diagnosis of possible **urticarial vasculitis** is recommended for urticarial lesions that persist at the same location for more than 24?hr or those with pigmented or purpuric components. Additional features suggestive of urticarial vasculitis include painful lesions, poor response to antihistamines, elevated ESR, and features of systemic illness such as fever and arthralgia. Collagen vascular diseases such as systemic lupus may manifest urticarial vasculitis as a presenting feature. The skin biopsy in urticarial vasculitis typically shows endothelial cell swelling of postcapillary venules with necrosis of the vessel wall, perivenular neutrophil infiltrate, diapedesis of red blood cells, and fibrin deposition associated with deposition of immune complexes.

The physical urticarias and clues for their identification should be considered in any patient with chronic urticaria (see Table 136–1). Papular urticaria commonly occurs in small children, generally on the extremities. It presents as grouped or linear highly pruritic wheals or papules mainly on exposed skin at the sites of insect bites. Mastocytosis is characterized by mast cell hyperplasia in the bone marrow, liver, spleen, lymph nodes, and skin. The disease is often associated with clinical effects of mast cell activation, including pruritus, flushing, urtication, abdominal pain, nausea, and vomiting. Urticaria pigmentosa is the most common skin manifestation of mastocytosis and may occur as an isolated skin finding. It appears as small, yellow-tan to reddish-brown macules or raised papules that urticate on scratching **(Darier sign).** The diagnosis is confirmed by a skin biopsy that shows increased numbers of dermal mast cells.

Exercise-induced anaphylaxis presents as varying combinations of pruritus, urticaria, angioedema, wheezing, laryngeal obstruction, or hypotension after exercise (see Chapter 137). Cholinergic urticaria is differentiated by positive results on heat challenge tests and the rare occurrence of anaphylactic shock. The combination of ingestion of various food allergens (shrimp, celery, wheat) and postprandial exercise has been associated with urticaria/angioedema. In such patients, food or exercise alone may not produce this reaction.

Muckle-Wells syndrome is a rare, dominantly inherited condition associated with recurrent urticaria, arthritis, and limb pain that usually appears in adolescence. It is associated with progressive nerve deafness, recurrent fever, elevated ESR, hypergammaglobulinemia, and renal amyloidosis. Eventually these patients develop generalized amyloidosis and die of this complication.

Treatment.

Acute urticaria is a self-limited illness requiring little treatment other than antihistamines. Hydroxyzine and diphenhydramine are effective sedating antihistamines commonly used for treatment of urticaria. Loratadine, fexofenadine, and cetirizine are also effective and may be preferable because of reduced frequency of drowsiness. Epinephrine 1:1,000, 0.01?mL/kg, maximum of 0.3?mL, usually provides rapid relief of acute, severe urticaria/angioedema. A short burst of corticosteroids should be given only for very severe episodes of urticaria and angioedema.

Most forms of physical urticaria respond to avoidance of triggering stimuli in combination with oral antihistamines. The exception is delayed pressure urticaria, which often requires oral corticosteroids. Cyproheptadine in divided doses is the drug of choice for cold-induced urticaria. Treatment of dermatographism consists of antihistamines; for severe symptoms, high doses may be needed. The initial objective of therapy is to decrease pruritus so that the stimulation for scratching is diminished. Sunscreens are the only effective treatment for solar urticaria.

The combined use of H_1 - and H_2 -type antihistamines is sometimes helpful to control chronic urticaria when H_1 -type antihistamines alone do not work. Doxepin, an antagonist of both H_1 and H_2 receptors, can be helpful. H_2 -type antihistamines alone may exacerbate urticaria. Perpetuation of the inflammatory response by cellular infiltration is critical to disease manifestations and degranulation of mast cells. When maximal H_1 -and/or H_2 -receptor blockade has been achieved, alternate-day therapy with corticosteroids is the most effective treatment. In general, prednisone, 20?mg orally as a single morning dose on alternate days, is used; the dosage is decreased by 2.5–5.0?mg every 3 wk depending on the patient's response. The goal is a slow gradual decline in dosage toward discontinuing therapy. Antileukotriene agents, in

combination with antihistamines, may also be helpful. Treatment with small doses of cyclosporine has been effective in some adults with chronic urticaria, but use of large doses has been limited by nephrotoxicity. Chronic urticaria does not often respond favorably to dietary manipulation. However, in refractory patients, removal of urticarial aggravators, such as salicylates or alcohol, should be considered. Treatment of autoimmune chronic urticaria refractory to medical therapy includes intravenous immunoglobulin or plasmapheresis, or both. Plaquenil has been found to be effective for hypocomplementemic urticarial vasculitis syndrome associated with autoantibodies to C1q.

Chapter 137 - Anaphylaxis

Hugh A. Sampson
Donald Y. M. Leung

Anaphylaxis is a clinical condition in which there is a sudden release of potent biologically active mediators from mast cells and basophils leading to cutaneous (urticaria, angioedema, flushing), respiratory (bronchospasm, laryngeal edema), cardiovascular (hypotension, dysrhythmias, myocardial ischemia), and gastrointestinal symptoms (nausea, colicky abdominal pain, vomiting, diarrhea). The overall annual incidence of anaphylaxis in the United States is estimated at 30 cases/100,000 persons/year (81,000 cases per year). An Australian parental survey found that 0.59% of children 3–17 yr of age experienced at least one anaphylactic event.

Etiology.

The most common causes of anaphylaxis in children differ depending on whether the population surveyed represents in-hospital patients or outpatients. Anaphylaxis occurring in the hospital is primarily the result of allergic reactions to medications and latex, whereas food allergy is the most common cause of anaphylaxis occurring outside the hospital, with about one half of the anaphylactic reactions reported in pediatric surveys from the United States, Italy, and South Australia (Box 137–1). Peanut allergy is becoming the major cause of food-induced anaphylaxis in “Westernized” countries, accounting for the majority of fatal and near-fatal reactions. In the hospital, latex is a particular problem for children undergoing multiple operations, such as patients with spina bifida and urologic disorders, and has prompted many hospitals to switch to latex-free products. Patients with latex allergy also may experience food allergic reactions from homologous proteins in fruits such as bananas, kiwi, avocado, chestnut, and passion fruit.

Pathogenesis.

Principal pathologic features in fatal anaphylaxis include acute pulmonary hyperinflation, edema and intra-alveolar hemorrhaging, visceral congestion, laryngeal edema, and urticaria and angioedema. Acute hypotension is attributed to vasomotor dilation and/or cardiac dysrhythmias.

Box 137-1. Etiology of Anaphylaxis in Children

IN-HOSPITAL

Latex

Antibiotics (especially intravenous)

Intravenous immune globulin

Radiocontrast dye

OUTSIDE OF HOSPITAL

Food (peanut, tree nuts, shellfish, milk, egg)

Insect sting (Hymenoptera, fire ants)

Oral medications (penicillins)

Exercise (including food-associated)

Idiopathic

Most cases of anaphylaxis are the result of activation of mast cells and basophils via cell-bound allergen-specific IgE molecules. As with any IgE-mediated reaction, patients must first be exposed to the responsible allergen to generate allergen-specific antibodies. In many cases the child and the parent are unaware of the initial exposure, which may be passage of food proteins in maternal breast milk. When re-exposed to the sensitizing allergen, mast cells and basophils, and possibly other cells such as macrophages, release a variety of mediators (e.g., histamine, tryptase) and cytokines that can produce allergic symptoms in any or all target organs. Clinical anaphylaxis also may be due to mechanisms other than IgE-mediated reactions, sometimes termed **anaphylactoid reactions**, including direct release of mediators from mast cells by medications and physical factors (e.g., morphine, exercise, cold), disturbances of leukotriene metabolism (aspirin and nonsteroidal anti-inflammatory drugs), immune aggregates and complement activation (blood products), and probable complement activation (e.g., radiocontrast dyes, dialysis membranes).

Clinical Manifestations and Diagnosis.

The diagnosis of anaphylaxis is usually apparent owing to the acute and dramatic nature of this disorder. The onset of symptoms may vary somewhat depending on the cause of the reaction; reactions from ingested allergens (foods, medications) are delayed in onset (minutes to 2?hr) compared with injected allergen (insect sting, medications) and tend to have more gastrointestinal symptoms. With the initiation of symptoms, patients may experience pruritus about the mouth and face, a sensation of warmth, weakness, and apprehension. They may develop flushing, urticaria and angioedema, oral pruritus, tightness in the throat, dry staccato cough and hoarseness, periocular pruritus, nasal congestion, sneezing, dyspnea, deep cough, and wheezing. Nausea, abdominal cramping, and vomiting are common with ingested allergens. Uterine contractions, which are manifest as lower back pain, are not uncommon in women, and faintness and loss of consciousness typically occur in severe cases. Some degree of obstructive laryngeal edema is typically encountered with severe reactions. Cutaneous symptoms may be absent, and the acute onset of severe bronchospasm in a previously well asthmatic should suggest the diagnosis of anaphylaxis.

Sudden collapse in the absence of cutaneous symptoms should also raise suspicion of vasovagal collapse, myocardial infarction, aspiration, pulmonary embolism, or seizure disorder. Laryngeal edema, especially with abdominal pain, suggests hereditary angioedema (see Chapter 124.3).

Laboratory Findings.

Laboratory studies may indicate the presence of IgE antibodies to a suspected causative agent, but this is not definitive. Plasma histamine is elevated for a brief period but is unstable and difficult to measure in a clinical setting. Plasma ß-tryptase is more stable and remains elevated for several hours but is usually not elevated in food-induced anaphylactic reactions.

Treatment.

Anaphylactic reaction should be managed aggressively (Box 137–2) with *intramuscular* epinephrine, intramuscular or intravenous H_1 and H_2 antihistamine antagonists, oxygen, intravenous fluids, inhaled ß-agonists, and corticosteroids. Patients may experience a biphasic reaction, which occurs when anaphylactic symptoms recur after apparent resolution. The mechanism of this phenomenon is unknown, but it appears to be more common when therapy is initiated late and symptoms at presentation are more severe. It does not appear to be affected by the administration of corticosteroids during the initial therapy. Over 90% of biphasic responses occur within 4?hr, so patients should be observed for at least 4?hr before being discharged from the emergency department.

Prevention.

Patients experiencing anaphylactic reactions to foods must be educated in allergen

avoidance, including actively

Box 137-2. Management of Patient with Anaphylaxis

TREATMENT OF REACTION

Dependent on severity of patient's symptoms

Patient

Injectable epinephrine (dependent on history and symptoms)

Oral liquid diphenhydramine (1?mg/kg up to 75?mg)

Transport to emergency facility

Emergency

Supplemental oxygen and airway management

Personnel

Epinephrine IM (IV for severe hypotension)

Intravenous fluid expansion

H_1 antagonist (diphenhydramine)—oral, IM, or IV

Corticosteroids—oral prednisone (1–2?mg/kg up to 75?mg) or intravenous methylprednisolone

H_1 antagonist (diphenhydramine)—oral, IM, or IV

Corticosteroids—oral prednisone (1–2?mg/kg up to 75?mg) or intravenous methylprednisolone
(1–2?mg/kg up to 125?mg)

Nebulized albuterol

H_2 antagonist (ranitidine)—oral or IV

POST REACTION

H_1 antagonist—cetirizine, fexofenadine, or loratadine for 3 days

Corticosteroids—oral prednisone 1?mg/kg (up to 75?mg) daily for 3 days

PREVENTATIVE TREATMENT

Follow-up evaluation for etiology

Immunotherapy for insect sting allergy

Prescription for EpiPen and antihistamine

PATIENT EDUCATION

Avoidance of causative agent

Recognition of early signs of anaphylaxis

Early treatment of allergic symptoms (anaphylaxis)

reading food labels and knowledge of potential contamination and high-risk situations, as well as in early recognition of anaphylactic symptoms and ready administration of emergency medications. Any child with food allergy and a history of asthma or previous severe anaphylactic reaction should be given an EpiPen, liquid diphenhydramine, and a written emergency plan in case of accidental ingestion. A form can be downloaded from the Food Allergy & Anaphylaxis Network at www.foodallergy.org. Patients with egg allergy should be tested before receiving the

influenza or yellow fever vaccines, which contain egg protein. Children experiencing systemic anaphylactic reactions to an insect sting should be evaluated and treated with immunotherapy, which is more than 90% protective. In cases of food-associated exercise-induced anaphylaxis, children must not exercise within 2–3?hr of ingesting the triggering food and, like children with exercise-induced anaphylaxis, they should exercise with a friend, learn to recognize the early signs of anaphylaxis (sensation of warmth and facial pruritus) and stop exercising, and seek help immediately if symptoms develop. Any child who is at risk for anaphylaxis should receive emergency medications, education, and a written emergency plan in case of accidental ingestion.

Reactions to medications can be reduced and minimized by using oral medications in preference to injected forms. New hypo-osmolar radiocontrast dyes can be used in cases where previous reactions are suspected. The use of powder-free, low-allergen gloves and materials should be used in children undergoing multiple surgeries.

Chapter 138 - Serum Sickness

Scott H. Sicherer
Donald Y. M. Leung

Serum sickness is a systemic, immune complex–mediated hypersensitivity vasculitis classically attributed to the therapeutic administration of foreign serum proteins.

Etiology.

In 1905, von Pirquet and Schick gave the first detailed description of the disorder in children treated with horse serum containing diphtheria antitoxin. Animal models later showed that immune complexes involving heterologous serum proteins and complement activation were important pathogenic mechanisms. Reactions described as “serum sickness–like” are now attributed more commonly to drug allergy, triggered in particular by antibiotics (e.g., penicillin, cefaclor) and rarely to other agents such as human gamma globulin and insect venom. For many disorders, the availability of alternative medical therapies, bioengineered antibodies, and biologicals of human origin have supplanted the use of nonhuman antisera. However, antibody therapies derived from the horse are available for treatment of envenomation by the black widow spider and a variety of snakes, botulism in adults, diphtheria infection, and immunosuppression (antithymocyte globulin).

Pathogenesis.

Serum sickness is a classic example of a Gell and Coombs type III hypersensitivity reaction caused by antigen-antibody complexes. In the rabbit model using bovine serum albumin as the antigen, symptoms develop with the appearance of antibody against the injected antigen. As free antigen concentration falls and antibody production increases over days, antigen-antibody complexes of various sizes develop in a manner analogous to a precipitin curve. While small complexes usually circulate harmlessly and large ones are cleared by the reticuloendothelial system, intermediate-sized complexes that develop at the point of slight antigen excess may deposit in blood vessel walls and tissues. There the immune microprecipitates induce vascular and tissue damage through activation of complement and granulocytes.

Complement activation (C3a, C5a) promotes chemotaxis and adherence of neutrophils to the site of immune complex deposition. The process of immune

complex deposition and of neutrophil accumulation may be facilitated by increased vascular permeability, owing to the release of vasoactive amines from tissue mast cells. Mast cells may be activated by binding of antigen to IgE or through contact with anaphylatoxins (C3a). Tissue injury results from the liberation of proteolytic enzymes and oxygen radicals from the neutrophils.

Clinical Manifestations.

The symptoms of serum sickness generally begin 7–12 days after injection of the foreign material but may appear as late as 3 wk afterward. The onset of symptoms may be accelerated if there has been earlier exposure or previous allergic reaction to the same antigen. A few days before the onset of generalized symptoms, the site of injection may become edematous and erythematous. Symptoms usually include fever, malaise, and rashes. Urticaria and morbilliform rashes are the predominant types of skin eruptions, and pruritus is common. In a prospective study of serum sickness induced by administration

of equine antithymocyte globulin, an initial rash was noted in most patients that began as a thin serpiginous band of erythema along the sides of the hands, fingers, feet, and toes at the junction of the palmar or plantar skin with the skin of the dorsolateral surface. In most patients, the band of erythema was replaced by petechiae or purpura, presumably because of low platelet counts. Additional symptoms include edema, myalgia, lymphadenopathy, arthralgia or arthritis involving multiple joints, and gastrointestinal complaints including pain, nausea, diarrhea, and melena. The disease generally runs a self-limited course, with recovery in 1–2 wk. Carditis, glomerulonephritis, Guillain-Barré syndrome, and peripheral neuritis are rare complications.

Diagnosis.

Circulating immune complexes are usually detectable with peak levels at 10–12 days. Serum complement levels (C3 and C4) are generally decreased and reach a nadir at about day 10. C3a anaphylatoxin may be increased. The erythrocyte sedimentation rate is usually elevated, and thrombocytopenia is often present. Mild proteinuria, hemoglobinuria, and microscopic hematuria may be seen. In serum sickness caused by horse serum proteins, antibodies of the IgG, IgA, IgM, and IgE classes may be found directed against various horse serum proteins. Direct immunofluorescence studies of skin lesions often reveal immune deposits of IgM, IgA, IgE, or C3.

Treatment.

Treatment is primarily supportive with antihistamines and analgesics, if needed. When the symptoms are especially severe, systemic corticosteroids can be used. High doses are given and rapidly reduced as the patient improves. The utility of extracorporeal removal of circulating immune complexes via plasmapheresis requires further study.

Prevention.

The primary mode of prevention of serum sickness is to seek alternative therapies, if they are available. In some cases, non–equine-derived formulations may be available in limited supply (e.g., human-derived botulinum immune globulin). Other emerging alternatives include partially digested antibodies of animal origin and engineered (humanized) antibodies. However, the potential of these therapies to elicit serum sickness–like disease remains to be determined. When only equine antitoxin/antivenom is available, skin tests should be performed before administration of serum. The results of allergy skin tests reflect primarily the risk of acute anaphylactic reactions to the serum proteins with a positive test indicating an increased likelihood and a negative test indicating a small, but not absent, risk of anaphylaxis. Testing generally begins with prick-puncture using a 1:100 dilution of the serum with positive (histamine) and negative (saline) controls and proceeds through several increasingly higher doses until a positive response is seen or a top dose of 0.02?mL of a 1:100 dilution injected intracutaneously is reached. A negative response to the strongest solution indicates that anaphylactic sensitivity to horse serum is unlikely. Unfortunately, skin tests do not predict the likelihood of development of serum sickness.

For patients who have evidence of anaphylactic sensitivity to horse serum, a risk to benefit assessment must be made to determine the need to proceed with treatment despite an increased risk for anaphylaxis. If needed, the serum can usually be successfully administered by a process of rapid desensitization. The suggested desensitization procedure varies slightly by manufacturer, by estimated degree of sensitivity, and by route (intravenous versus intramuscular/subcutaneous). Starting doses are usually quite small (e.g., 0.1?mL of serum diluted to 1:100,000–1:1,000) and administered in gradually increasing increments such as doubling doses at 15–20?min intervals, as tolerated, until the required cumulative dose is achieved. Generally, the entire amount of antitoxin can be administered safely over a 4–6?hr period. Desensitization is transient, and the patient may regain the previous anaphylactic sensitivity in the months after treatment. Serum sickness is not prevented by desensitization or pretreatment with methylprednisolone.

Chapter 139 - Adverse Reactions to Drugs

Mark Boguniewicz

Adverse drug reactions are being increasingly recognized in the pediatric population as the number of drugs approved for use in this population increases. Adverse drug reactions can be divided into predictable and unpredictable reactions. **Predictable reactions** including drug toxicity, drug interactions, and adverse effects are dose dependent, can be related to known pharmacologic actions of the drug, and occur in patients without any unique susceptibility. In contrast, **unpredictable reactions** are dose independent, often not related to the pharmacologic actions of the drug, and occur in susceptible patients. These include idiosyncratic reactions, allergic (hypersensitivity) reactions, and pseudoallergic reactions. **Pseudoallergic reactions** resemble allergic reactions but are distinguished by the fact that an immunologic mechanism is not involved. Allergic reactions require prior sensitization, manifest with signs or symptoms characteristic of an underlying allergic mechanism, such as anaphylaxis or urticaria, and occur in genetically susceptible individuals. They can occur at doses significantly below the therapeutic range.

Epidemiology.

The incidence of adverse drug reactions in the general as well as pediatric populations remains unknown, although data from hospitalized patients shows it to be 6.7%, with a 0.32% incidence of fatal adverse drug reactions. Cutaneous reactions are the most common form of adverse drug reactions with ampicillin, amoxicillin, penicillin, and trimethoprim-sulfamethoxazole accounting for the majority of implicated drugs. Although the majority of adverse drug reactions do not appear to be allergic in nature, 6–10% can be attributed to an allergic or immunologic mechanism.

Pathogenesis and Clinical Manifestations.

Immunologically mediated adverse drug reactions have been classified according to the **Gell and Coombs classification**: immediate hypersensitivity reactions (type I), cytotoxic antibody reactions (type II), immune complex reactions (type III), and delayed-type hypersensitivity reactions (type IV). Immediate hypersensitivity reactions occur when a drug or drug metabolite interacts with preformed drug-specific IgE antibodies that are bound to the surfaces of tissue mast cells

and/or circulating basophils. The cross-linking of adjacent receptor-bound IgE by antigen causes the release of preformed and newly synthesized mediators such as histamine and leukotrienes that contribute to the clinical development of urticaria, bronchospasm, or anaphylaxis. Cytotoxic reactions involve IgG or IgM antibodies that recognize drug antigen on cell membrane. In the presence of serum complement, the antibody coated cell is either cleared by the monocyte-macrophage system or is destroyed. Examples include drug-induced hemolytic anemia or thrombocytopenia. Immune complex reactions are caused by soluble complexes of drug or metabolite in slight antigen excess with IgG or IgM antibodies.

The immune complex is deposited in blood vessel walls and causes injury by activating the complement cascade as seen in serum sickness. Clinical manifestations include fever, urticaria, rash, lymphadenopathy, and arthralgias. Symptoms typically appear 1–3 wk after the last dose of an offending drug and subside when the drug and/or its metabolite are cleared from the body. Delayed-type hypersensitivity reactions are mediated by drug-specific T lymphocytes. Sensitization usually occurs via the topical route of administration, resulting in allergic contact dermatitis. Commonly implicated drugs include neomycin and local anesthetics in topical formulations. Certain adverse drug reactions including drug fever or the morbilliform rash seen with use of ampicillin or amoxicillin in the setting of Epstein-Barr virus infection are not easily classified. Recent studies point to the role of T cells and eosinophils in delayed maculopapular reactions to a number of antibiotics.

DRUG METABOLISM AND ADVERSE REACTIONS.

Most drugs and their metabolites are not immunologically detectable until they have become covalently attached to a macromolecule. This multivalent hapten-protein complex forms a new immunogenic epitope that can elicit T and B lymphocyte responses. The penicillins and related ß-lactam antibiotics are highly reactive with proteins and can directly haptenate protein carriers, which may account for the frequency of immune-mediated hypersensitivity reactions with this class of antibiotics.

Incomplete or delayed metabolism of some drugs can give rise to toxic metabolites. Hydroxylamine, a reactive metabolite produced by cytochrome P-450 oxidative metabolism, may mediate adverse reactions to sulfonamides. Patients who are slow acetylators appear to be at increased risk. In addition, cutaneous reactions in patients with AIDS treated with trimethoprim- sulfamethoxazole, rifampin, or other drugs may be due to glutathione deficiency resulting in toxic metabolites. Serum sickness–like reactions in which immune complexes have not been documented, which occur most commonly with cefaclor, may result from an inherited propensity for hepatic biotransformation of drugs into toxic or immunogenic metabolites.

RISK FACTORS FOR HYPERSENSITIVITY REACTIONS.

Risk factors for adverse drug reactions include previous exposure, previous reaction, age (20–49 yr), route of administration (parenteral or topical), dose (high), and dosing schedule (intermittent), as well as genetic predisposition (slow acetylators). Atopy does not appear to predispose patients to allergic reactions to low molecular weight compounds, but atopic patients who develop an allergic reaction have a significantly increased risk of serious reaction. Atopic patients also appear to be at greater risk for pseudoallergic reactions induced by radiocontrast media. Pharmacogenomics will likely play an increasing role in identifying individuals at risk for certain drug reactions.

Diagnosis.

An accurate medical history is an important first step in evaluating a patient with a possible adverse drug reaction. Suspected drugs need to be identified with dosages, route of administration, previous exposures, and dates of administration. In addition, underlying hepatic or renal disease may influence drug metabolism. For past reactions, a detailed description may yield clues to the nature of the adverse drug reaction. The propensity for a particular drug to cause the suspected reaction can be checked with information in the *Physicians' Desk Reference*, the *Drug Eruption Reference Manual*, or directly from the drug manufacturer. However, it is important to remember that the history may be unreliable and many patients are inappropriately labeled as being drug allergic, which can result in inappropriate withholding of a needed drug or class of drugs. In addition, relying solely on the history can lead to overuse of drugs reserved for special indications such as vancomycin in patients suspected of penicillin allergy. In fact, approximately 80% of patients with a history of penicillin allergy will not have evidence of penicillin-specific IgE antibodies on testing.

Skin testing is the most rapid and sensitive method of demonstrating the presence of IgE antibodies to a specific allergen. It can be performed with high molecular weight compounds such as foreign antisera, hormones, enzymes, and toxoids. Reliable skin testing can also be performed with penicillin, but not with most other antibiotics. Most immunologically mediated adverse drug reactions are due to metabolites rather than to parent compounds, and the metabolites for most drugs other than penicillin have not been defined. In addition, many metabolites are unstable or must combine with larger proteins to be useful for diagnosis. Testing with nonstandardized reagents requires caution in interpretation of both positive and negative results because some drugs can induce nonspecific irritant reactions. Whereas a wheal-and-flare reaction is suggestive of drug-specific IgE antibodies, a negative skin test does exclude the presence of such antibodies because the relevant immunogen may not have been used as the testing reagent.

A positive skin test to the major or minor determinants of penicillin has a 60% positive predictive value for an immediate hypersensitivity reaction to penicillin. If skin tests to the major and minor determinants of penicillin are negative, 97–99% of patients (depending on the reagents used) will tolerate the drug without risk of an immediate reaction. The positive and negative predictive values of skin testing to antibiotics other than penicillin are not well established. Nevertheless, positive immediate hypersensitivity skin tests to nonirritant concentrations of nonpenicillin antibiotics may be interpreted as a presumptive risk of an immediate reaction to such agents.

Direct and indirect Coombs tests are often positive in drug-induced hemolytic anemia. Assays for specific IgG and IgM have been shown to correlate with a drug reaction in immune cytopenias, but in most other reactions such assays are not

diagnostic. In general, many more patients express humoral or T-cell immune responses to drug determinants than express clinical disease. Serum tryptase is elevated with systemic mast cell degranulation and can be seen with drug associated mast cell activation, although it is not pathognomonic for drug hypersensitivity and nonelevated tryptase levels can be seen in well-defined anaphylaxis.

Treatment.

Specific **desensitization,** which involves the progressive administration of an allergen to render effector cells less reactive, is reserved for patients with IgE antibodies to a particular drug for whom an alternative drug is not available or appropriate. Specific protocols for many different drugs have been described. Desensitization should be performed in a hospital setting usually in consultation with an allergist with resuscitation equipment available at all times. While mild complications, such as pruritus or rash, are fairly common and often respond to adjustments in the drug dose or dosing intervals and medications to relieve symptoms, more severe systemic reactions can occur. Oral desensitization may be less likely to induce anaphylaxis than parenteral administration. Pretreatment with antihistamines and/or corticosteroids usually is not recommended.

Graded challenges based on the administration of a drug in an incremental fashion until a therapeutic dose is achieved can be attempted with drugs causing non–IgE-mediated reactions, including trimethoprim-sulfamethoxazole. Graded challenges in aspirin- or nonsteroidal anti-inflammatory drug (NSAID)-intolerant patients, particularly those with respiratory reactions, can also be performed. Gradual introduction of a drug may reveal systemic intolerance early enough to prevent progression to a serious or even life-threatening reaction such as Stevens-Johnson syndrome or toxic epidermal necrolysis.

ß-LACTAM HYPERSENSITIVITY.

Penicillin is a frequent cause of anaphylaxis and is responsible for the majority of all drug-mediated anaphylactic deaths in the United States. Although IgE-mediated reactions may occur after administration of penicillin by any route, parenteral administration is more

likely to cause anaphylaxis. If a patient requires penicillin and has a past history suggestive of penicillin allergy, it is necessary to skin test the patient for the presence of penicillin-specific IgE with both the major and minor determinants of penicillin. Skin tests to both major and minor determinants of penicillin are necessary because about 20% of patients with documented anaphylaxis do not demonstrate skin reactivity to the major determinant. While the major determinant is available commercially (PrePen), minor determinant mixtures are currently not licensed and are synthesized at select centers. Although penicillin G is often used as a substitute for minor determinant mixture, with this approach there is a small but significant risk of false-negative skin test results. Thus, patients should be referred to an allergist capable of performing appropriate testing. If the skin test is positive to either major or minor determinants of penicillin, the patient should receive an alternative non–cross-reacting antibiotic. If administration of penicillin is deemed necessary, desensitization by an allergist in an appropriate medical setting can be performed. Skin testing for penicillin-specific IgE is not predictive for delayed onset cutaneous, bullous, or immune complex reactions. In addition, penicillin skin testing does not appear to resensitize the patient.

Other ß-lactam antibiotics including semisynthetic penicillins, cephalosporins, carbacephems, carbapenems, and monobactams share the ß-lactam ring structure. Patients with late-onset morbilliform rashes with amoxicillin are not considered to be at risk for IgE-mediated reactions to penicillin and do not require skin testing before penicillin administration. Patients with Epstein-Barr virus infections treated with ampicillin or amoxicillin can develop a nonpruritic rash in up to 100% of cases. Similar reactions occur in patients with elevated uric acid treated with allopurinol or with chronic lymphocytic leukemia. If the rash to ampicillin or amoxicillin is urticarial or systemic, or the history is unclear, the patient should undergo penicillin skin testing if a penicillin is needed. There have been reports of antibodies specific for semisynthetic penicillin side chains in the absence of ß-lactam ring-specific antibodies, although the clinical significance of such side chain–specific antibodies is unclear.

Varying degrees of in vitro cross reactivity have been documented between cephalosporins and penicillins. Although the risk of allergic reactions to cephalosporins in patients with positive skin tests to penicillin appears to be low (<2%), anaphylactic reactions have occurred after administration of cephalosporins in patients with a positive history of penicillin anaphylaxis. If a patient has a history of penicillin allergy and requires a cephalosporin, skin testing to major and minor determinants of penicillin should preferably be performed to determine if the patient has penicillin-specific IgE antibodies. If skin tests are negative, the patient can receive a cephalosporin with no greater risk than the general population. If skin tests are positive to penicillin, recommendations may include administration of an alternative antibiotic; cautious graded challenge with appropriate monitoring, recognizing that there may be a 2% chance of inducing an anaphylactic reaction; or desensitization to the required cephalosporin.

Conversely, patients who require penicillin and have a history of an IgE-mediated reaction to a cephalosporin should also undergo penicillin skin testing. If the tests are negative, they can receive penicillin; if positive, they should either receive an alternative medication or undergo desensitization to penicillin. In patients with a history of allergic reaction to one cephalosporin requiring another cephalosporin, skin testing with the required cephalosporin can be performed, recognizing that the negative predictive value is unknown. If the skin test to the cephalosporin is positive, the significance of the test should be checked further in control subjects to determine if the positive response is IgE mediated or an irritant response. The drug can then be administered by graded challenge or desensitization.

Carbapenems (imipenem and meropenem) represent another class of ß-lactam antibiotics with a bicyclic nucleus that demonstrate a high degree of cross reactivity with penicillins. In contrast to the other ß-lactam antibiotics, monobactams (aztreonam) have a monocyclic ring structure. Aztreonam-specific antibodies have been shown to be predominantly side-chain specific; data suggest that aztreonam can be safely administered to most penicillin-allergic subjects.

SULFONAMIDES.

The most common type of reaction to sulfonamides is a maculopapular eruption often associated with fever that occurs after 7–12 days of therapy. Immediate reactions including anaphylaxis as well as other immunologic reactions have also been suggested. For those individuals who develop maculopapular rashes after sulfonamide administration, both graded challenge and desensitization protocols have been shown to be effective. These regimens should not be used in individuals with a history of Stevens-Johnson syndrome or toxic epidermal necrolysis. Hypersensitivity reactions to sulfasalazine, for treatment of inflammatory bowel disease, appear to result from the sulfapyridine moiety. Slow desensitization over approximately 1 mo permits tolerance of the drug in many patients. In addition, oral and enema forms of 5-ASA, thought to be the pharmacologically active agent in sulfasalazine, are effective alternative therapies.

STEVENS-JOHNSON SYNDROME AND TOXIC EPIDERMAL NECROLYSIS.

Blistering mucocutaneous disorders induced by drugs encompass a spectrum of reactions, including Stevens-Johnson syndrome and toxic epidermal necrolysis. Epidermal detachment of less than 10% is suggestive of Stevens-Johnson syndrome, detachment of 30% suggests toxic epidermal necrolysis, and 10–30% detachment suggests overlap of the two syndromes. The features of Stevens-Johnson syndrome include confluent purpuric macules on face and trunk and severe, explosive mucosal erosions, usually at more than one mucosal surface, accompanied by fever and constitutional symptoms. Ocular involvement may be particularly severe, and the liver, kidneys, and lungs may also be involved. Toxic epidermal necrolysis, which appears to be related to keratinocyte apoptosis, manifests with widespread areas of confluent erythema followed by epidermal necrosis and detachment with severe mucosal involvement. The risk of infection and mortality are high. Skin biopsy differentiates subepidermal cleavage characteristic of toxic epidermal necrolysis from intraepidermal cleavage characteristic of the scalded skin syndrome induced by staphylococcal toxins. The effectiveness of corticosteroids in the treatment of Stevens-Johnson syndrome is controversial, but, if used, they should be started as early in the course of the disease as possible. Toxic epidermal necrolysis must be treated in a burn unit. Corticosteroids are contraindicated because they can significantly increase the risk of infection. High intravenous doses of immunoglobulin have been shown to be beneficial in patients with toxic epidermal necrolysis likely due to inhibition of Fas-mediated keratinocyte cell death by naturally occurring Fas blocking antibodies in the intravenous immunoglobulin preparation.

PERIOPERATIVE AGENTS.

Anaphylactoid reactions occurring during general anesthesia may be caused by induction agents (thiopental) or muscle-relaxing agents (succinylcholine, pancuronium). Quaternary ammonium muscle relaxants (e.g., succinylcholine) can act as bivalent antigens in IgE-mediated reactions. Negative skin tests do not necessarily predict that a drug will be tolerated. Latex allergy should always be considered in the differential diagnosis of a perioperative reaction.

LOCAL ANESTHETICS.

Adverse drug reactions associated with local anesthetic agents are primarily toxic reactions resulting from rapid drug absorption, inadvertent intravenous injection, or overdosage. Local anesthetics are classified as esters of benzoic acid (group I) or amides (group II). Group I includes benzocaine and procaine; group II includes lidocaine, bupivacaine,

and mepivacaine. In suspected local anesthetic allergy, skin testing followed by a graded challenge can be performed or an anesthetic agent from a different group can be used.

INSULIN.

Insulin use has been associated with a spectrum of adverse drug reactions, including local and systemic IgE-mediated reactions, hemolytic anemia, serum sickness reactions, and delayed-type hypersensitivity. In general, human insulin is less allergenic than porcine insulin, which is less allergenic than bovine insulin, but for individual patients porcine or bovine insulin may be the least allergenic. Patients treated with nonhuman insulin have had systemic reactions to recombinant human insulin even on the first exposure. More than 50% of patients who receive insulin develop antibodies against the insulin preparation, although there may not be any clinical manifestations. Local cutaneous reactions usually do not require treatment and resolve with continued insulin administration, possibly owing to IgG blocking antibodies. More severe local reactions can be treated with antihistamines or by splitting the insulin dose between separate administration sites. Local reactions to the protamine component of NPH insulin may be avoided by switching to Lente insulin. Immediate-type reactions to insulin, including urticaria and anaphylactic shock, are unusual and almost always occur after reinstitution of insulin therapy in sensitized patients. Insulin therapy should not be interrupted if a systemic reaction to insulin occurs and continued insulin therapy is essential. Skin testing may identify a less antigenic insulin preparation. The dose following a systemic reaction is usually reduced to one third, and successive doses are increased in 2–5 unit increments until the dose resulting in diabetic control is attained; insulin skin testing and desensitization are required if insulin treatment is subsequently interrupted for more than 24–48?hr. Immunologic resistance usually occurs when a patient develops high titers of predominantly IgG antibodies to insulin. A rare form of insulin resistance caused by circulating antibodies to tissue insulin receptors is associated with acanthosis nigricans and lipodystrophy. Coexisting insulin allergy may be present in up to one third of patients with insulin resistance. Approximately half of affected patients benefit from substitution with a less reactive insulin preparation, based on skin testing.

ANTICONVULSANT HYPERSENSITIVITY SYNDROME.

Anticonvulsant hypersensitivity syndrome is a potentially life-threatening syndrome

that occurs with exposure of variable lengths to anticonvulsant medications. It appears to result from an inherited deficiency of epoxide hydrolase, an enzyme required for the metabolism of arene oxide intermediates produced during hepatic metabolism of anticonvulsant drugs. It is characterized by fever, maculopapular rash, and generalized lymphadenopathy along with visceral organ involvement. Drug-induced hypersensitivity syndrome has also been described with minocycline, sulfonamides, and dapsone.

RED MAN SYNDROME.

This syndrome most commonly described with administration of vancomycin is caused by nonspecific histamine release. It can be prevented by slowing the rate of intravenous infusion and/or preadministration of H_1 -blockers.

RADIOCONTRAST MEDIA.

Anaphylactoid reactions to radiocontrast media (RCM) or dye can occur after intravascular administration and during myelograms or retrograde pyelograms. No single pathogenic mechanism has been defined, but it is likely that mast cell activation accounts for the majority of these reactions. Complement activation has also been described. There is no evidence that sensitivity to seafood or iodine predisposes to RCM reactions. Although predictive tests are not available, patients with atopic profiles and those using ß-blockers appear to be at increased risk for RCM reactions. Patients who have experienced anaphylactoid reactions during the administration of RCM are at increased risk for recurrence with re-exposure. Other diagnostic alternatives should be considered or patients can be given low osmolality RCM with a pretreatment regimen including oral prednisone, diphenhydramine, and albuterol, with or without cimetidine or ranitidine.

NARCOTIC ANALGESICS.

Opiates such as morphine and related narcotics can induce direct mast cell degranulation. Patients may develop generalized pruritus, urticaria, and, occasionally, wheezing. If there is a suggestive history and analgesia is required, a non-narcotic medication should be considered. If this does not control pain, graded challenge with an alternative opiate is an option.

ASPIRIN AND NSAIDS.

Aspirin and NSAIDs can cause anaphylactoid reactions or urticaria and/or angioedema in children and rarely asthma with or without rhinoconjunctivitis in adolescents. There is no skin or in vitro test to identify patients who may react to aspirin or other NSAIDs. Once aspirin or NSAIDs intolerance has been established, options include avoidance or pharmacologic desensitization and subsequent continued treatment with aspirin or NSAIDs if indicated. Preliminary studies suggest that cyclo-oxygenase-2 inhibitors are tolerated by patients with aspirin-induced asthma.

Chapter 140 - Insect Allergy

Scott H. Sicherer
Donald Y. M. Leung

Allergic reactions caused by inhalation of airborne particles of insect origin result in acute and chronic respiratory symptoms. The allergic responses to stinging or, more rarely, biting insects result in reactions that vary from those localized to the skin to systemic anaphylaxis.

Etiology.

IgE antibody–mediated allergic responses to airborne particulate matter carrying insect emanations contribute to seasonal and perennial symptoms affecting the upper and lower airway. Seasonal reactions are attributed to exposures to a variety of insects, particularly aquatic insects such as the caddis fly and midge at a time when larvae pupate and adult flies are airborne. The fine wing scales and other emanations from virtually any insect may induce symptoms in select environments; for example, the mayfly is responsible for allergic symptoms in the area around the western end of Lake Erie. In terms of perennial inhalant allergy, cockroach sensitization is associated with increased asthma morbidity for exposed children. The house dust mite plays a similar role as an indoor allergen, but these creatures, unlike the cockroach, have eight rather than six legs and are phylogenetically related to spiders rather than insects.

For insect bite reactions, induced for example by mosquitoes, flies, and fleas, the primary lesion is isolated to the area of the bite and generally does not represent an allergic response. Occasionally, insect bites or stings induce larger local reactions that may be based on immediate or delayed hypersensitivity reactions.

Systemic allergic responses to insects are attributed most typically to IgE antibody-mediated responses, which are caused almost entirely by stings from venomous insects of the order Hymenoptera. Members of this order include apids (honeybee, bumblebee), vespids (yellow jacket, wasp, hornet), and formicids (fire and harvester ants). Among winged stinging insects, yellow jackets are the most notorious for stinging because they are aggressive, are ground dwelling, and linger near human activities involving food. Hornets nest in trees, wasps build honeycomb nests in dark areas such as under porches, and both are aggressive if disturbed. Honeybees are less aggressive, nest in tree hollows, and, unlike the other flying Hymenoptera, almost always leave a barbed stinger with venom sac after an attack. In the United States, red or black fire ants are found in increasing areas of the southeast, living in large mounds of soil. When disturbed, the ants attack in large numbers, anchor themselves to the skin by their mandible and sting multiple times in a semi-circle pattern. Sterile pustules form at the sting sites. Systemic reactions to stinging insects occur in 0.4–0.8% of children and 3% of adults and account for approximately 40 deaths each year in the United States.

Pathogenesis.

A variety of proteins derived from insects can become airborne and induce IgE-mediated respiratory responses, causing inhalant allergies. For example, the primary allergenic substance from midge, or lake flies, derives from hemoglobin and the major allergen of caddis fly is a hemocyanin-like protein. Allergens from the cockroach are the best studied and are derived from cockroach saliva, secretions, fecal material, debris from skin casts, and dead cockroaches. Allergenic proteins from the cockroach include proteases, troponin, tropomyosin, and lipocalin.

Localized skin responses to biting insects are likely caused by vasoactive or irritant materials derived from the insect's saliva. There is no evidence for IgE involvement in the local reaction. Systemic IgE-mediated allergic reactions to salivary proteins of biting insects are reported, but uncommon.

Hymenoptera venoms contain numerous components with toxic and pharmacologic activity and with allergenic potential. These constituents include vasoactive materials such as histamine, acetylcholine, and kinins; enzymes such as phospholipase and hyaluronidase; apamin; melittin; and formic acid. The majority of patients who experience systemic reactions after Hymenoptera stings have IgE-mediated sensitivity to antigenic material in the venom. Some venom allergens are homologous among members of the Hymenoptera order; others are family specific. There is substantial cross reactivity among vespid venoms, but these are distinct from honeybee.

Clinical Manifestations.

Inhalant allergy caused by insects results in clinical disease that is similar to that induced by other inhalant allergens such as pollens or dust mite. Depending on individual sensitivity and exposure, reactions may result in perennial or seasonal rhinitis, conjunctivitis, and asthma.

Insect bites are usually urticarial but may be papular or vesicular. Papular urticaria affecting the lower extremities in children is usually caused by multiple bites. Occasionally, individuals develop large local reactions. IgE antibody–associated immediate- and late-phase allergic responses to mosquito bites sometimes mimic cellulitis.

Clinical reactions to stinging venomous insects are categorized as local, large local,

systemic, toxic, and delayed/late. Simple **local reactions** involve limited swelling, pain and generally last less than a day. **Large local reactions** develop over hours and days, involve swelling of extensive areas that are contiguous with the sting site, and may last for days. **Non–life-threatening systemic reactions** generally progress within minutes and include skin symptoms of urticaria, angioedema, and pruritus distal to the site of the sting. **Life-threatening, immediate systemic reactions** are identical to anaphylaxis from other triggers and include symptoms of laryngeal edema, bronchospasm, and hypotension. Stings from a large number of insects at once may result in **toxic reactions** of fever, malaise, emesis, and nausea owing to the chemical properties of the venom in large doses. Serum sickness, nephrotic syndrome, vasculitis, neuritis, or encephalopathy may occur as **delayed/ late reactions** to stinging insects.

Diagnosis.

In the case of inhalant allergy to insects, the diagnosis may be evident by a history of typical symptoms induced seasonally in specific geographic regions (e.g., mayfly induced allergy). A chronic respiratory symptom in the face of chronic exposure, as may occur for cockroach allergy, is a scenario that is less amenable to identification by history. Tests for specific IgE to the insect by skin prick or radioallergosorbent test (RAST) will confirm inhalant insect allergy. In the case of potential cockroach allergy in patients with persistent asthma and known cockroach exposure, allergy tests may be particularly warranted.

The diagnosis of allergy from biting and stinging insects is generally evident from the history of exposure, typical symptoms, and physical examination. The diagnosis of Hymenoptera allergy rests in part on the identification of venom-specific IgE antibody. The primary reasons to pursue testing are to confirm reactivity when venom immunotherapy (VIT) is being considered or when it is clinically necessary to confirm venom hypersensitivity as a cause of a reaction. Venoms of five Hymenoptera (honeybee, yellow jacket, yellow hornet, white-faced hornet, and wasp) and whole-body extracts of fire ant are available for skin testing and treatment. In the context of a convincing clinical history, appropriately performed skin testing is useful in identifying children at risk for systemic anaphylaxis. However, venom skin test negative subjects have been reported to experience anaphylaxis when re-stung. Although the skin tests are considered more sensitive for the detection of venom-specific IgE antibody compared with RAST, if they are negative in the presence of a convincing history it is reasonable to consider additional evaluation with repeat skin tests and RAST. With venom RAST, there is a 20% incidence of both false-positive and false-negative results so it would not be appropriate to exclude venom hypersensitivity based on RAST alone. As many as 40% of skin test–positive subjects may not experience anaphylaxis on sting challenge, so testing without an appropriate history is potentially misleading. Skin tests are usually accurate within 1 wk of a sting reaction, but occasionally a refractory period is observed that warrants re-testing after 4–6 wk if the initial tests were negative.

Treatment and Prevention.

Avoidance of the insect is the preferred management of inhalant allergy. This can prove difficult, particularly, for instance, for those living in multiple-dwelling apartments where eradication of cockroaches is problematic. Immunotherapy is occasionally undertaken but beneficial results have not been thoroughly documented.

For cutaneous reactions caused by biting insects and for local reactions to stings, treatment with cold compresses, topical medicaments to relieve itching, and occasionally the use of a systemic antihistamine and oral analgesic are appropriate. Stingers should be removed promptly by scraping with caution not to squeeze the venom sac because this could inject more venom. Sting sites rarely become infected, possibly owing to the antibacterial actions of venom constituents. If the vesicles left by fire ant stings are scratched open, cleansing to prevent secondary infection is appropriate.

Anaphylactic reactions after a Hymenoptera sting are treated in an identical fashion to anaphylaxis from any cause. Therapies may include epinephrine, antihistamines, blood volume expanders, and other treatments (see Chapter 137). Those who have had previous systemic reactions to Hymenoptera stings should have immediate access to self-injectable epinephrine. Adults responsible for allergic children, and older patients who can self-treat, must be carefully taught the indications for and technique of administration of this medication. Particular attention is necessary for children in out-of-home daycare centers, at school, or attending camps to ensure that an emergency action plan is in place. Patients at risk for anaphylaxis from an insect sting should also wear an identification bracelet indicating their allergy. To reduce the risk of stings, they should avoid attractants such as perfumes and bright-colored clothing outdoors, wear gloves when gardening, and wear long pants and shoes when walking in the grass or through fields. Typical insect repellents do not guard against Hymenoptera.

Hymenoptera VIT is highly effective (97%) in decreasing the risk for severe anaphylaxis. The selection of patients for VIT depends on several factors (Table 140–1). Individuals at any age with local reactions are not at increased risk for severe systemic reactions on a subsequent sting and are not candidates for VIT. Those who experience severe systemic reactions (airway involvement or hypotension) and have a positive skin test result should receive immunotherapy. Immunotherapy to winged Hymenoptera is not considered indicated for children younger than age 16 yr in whom stings have caused systemic reactions limited to the skin because their risk for anaphylaxis after a subsequent sting is about 10%, with isolated skin reactions as the most likely event. The risk could be reduced to 1.2% on VIT, so it is an option to consider if multiple future stings are anticipated. Immunotherapy to winged Hymenoptera is indicated in those older than age 17 yr if skin test results are positive to venom and there is a history of systemic reaction, even isolated urticaria, because the risk for future systemic reactions approaches 60%. VIT is usually not indicated if there is no evidence of IgE to venom. The incidence of adverse effects during the course of treatment is not trivial in adults; 50% experience large local reactions and about 7% experience systemic reactions. The incidence of both local and systemic reactions is much lower in children. It is uncertain how long immunotherapy with Hymenoptera venom should continue, but over 85% of adults who have received 5 yr of therapy tolerate challenge stings

without systemic reactions for 5–10 yr after completion of treatment.

Less is known about the natural history of fire ant hypersensitivity and efficacy of immunotherapy for this allergy. The criteria for starting immunotherapy are similar to that for other Hymenoptera, but it is controversial as to whether children younger than age 16 yr should receive treatment if they have

TABLE 140-1 -- **Indications for Venom Immunotherapy (VIT) to Winged Hymenoptera**

Symptoms	Age	Skin test/RAST	Venom Immunotherapy Indicated
Local or large local reaction	All	+ or -	No
Systemic reaction limited to the skin	=16 yr	+ or -	No
	=17 yr	+	Yes
		-	No
Systemic reaction beyond the skin	All	+	Yes
		-	No

RAST = radioallergosorbent test.

only experienced systemic reactions confined to the skin. Only whole-body extract is commercially available for diagnosis by allergy skin testing and for treatment by immunotherapy.

Chapter 141 - Ocular Allergies

Mark Boguniewicz

The eye is a common target of allergic disorders because of its marked vascularity and direct contact with the environment, with the conjunctiva being the most immunologically active tissue of the external eye. Ocular allergies can occur as isolated target organ disease or more commonly in conjunction with nasal allergies. Ocular symptoms can significantly affect quality of life.

Clinical Manifestations

ALLERGIC CONJUNCTIVITIS.

Allergic conjunctivitis is the most common hypersensitivity response of the eye, affecting approximately 25% of the general population and 30% of children with atopy. It is caused by direct exposure of the mucosal surfaces of the eye to environmental allergens. Patients complain of itchy eyes, rather than pain. Clinical signs include bilaterally injected conjunctivae with vascular congestion that may progress to **chemosis,** or conjunctival swelling, and a watery discharge. Allergic conjunctivitis occurs in a perennial, or more commonly, seasonal form. Seasonal allergic conjunctivitis is typically associated with allergic rhinitis and most commonly triggered by ragweed or grass pollens. Perennial allergic conjunctivitis is triggered by allergens such as animal danders or dust mites that are present throughout the year. Symptoms are usually not as severe as seen with seasonal allergic conjunctivitis.

VERNAL KERATOCONJUNCTIVITIS.

Vernal keratoconjunctivitis is a severe bilateral chronic inflammatory process of the upper tarsal conjunctival surface that occurs in a limbal or palpebral form. It may threaten eyesight if it involves the cornea. Although vernal keratoconjunctivitis is not IgE mediated, it occurs most frequently in children with seasonal allergies, asthma, or atopic dermatitis, with boys being affected twice as often as girls. Vernal keratoconjunctivitis is more common in persons of Asian and African origin. It has a marked seasonal incidence, especially in the springtime. Symptoms include intense pruritus exacerbated by exposure to irritants, light, or perspiration. In addition, patients may complain of photophobia, foreign-body sensation, and lacrimation. Giant papillae occur predominantly on the upper tarsal plate and are typically described as **cobblestoning.** Other signs include a stringy discharge, transient yellow-white points in the limbus **(Trantas dots)** and conjunctiva **(Horner points)** or corneal “shield” ulcers, and **Dennie lines** (Dennie-Morgan folds), which are prominent symmetric skinfolds that extend in an arc from the inner canthus beneath and parallel to the lower lid margin.

ATOPIC KERATOCONJUNCTIVITIS.

Atopic keratoconjunctivitis is a chronic inflammatory ocular disorder most commonly involving the lower tarsal conjunctiva. When it involves the cornea, it can lead to blindness. Almost all patients have atopic dermatitis, and a significant number have asthma. Atopic keratoconjunctivitis rarely presents before late adolescence. Symptoms include itching, burning, and tearing that

are much more severe than in allergic conjunctivitis and persist throughout the year. The bulbar conjunctiva is injected and chemotic. Eyelid eczema can extend to the periorbital skin and cheeks with erythema and thick, dry scales. Secondary staphylococcal blepharitis is common because of eyelid induration and maceration.

GIANT PAPILLARY CONJUNCTIVITIS.

Giant papillary conjunctivitis has been linked to chronic exposure to foreign bodies, such as contact lenses, both hard and soft, ocular prostheses, and sutures. Symptoms and signs include itching, tearing, and excessive ocular discomfort with mucus production along with white or clear exudate on awakening, which may become thick and stringy. Trantas dots, limbal infiltration, bulbar conjunctival hyperemia, and edema may develop.

CONTACT ALLERGY.

Contact allergy typically involves the eyelids but can also involve the conjunctivae. It is being recognized more frequently in association with increased exposure to topical medications, contact lens solutions, and preservatives.

Diagnosis.

Nonallergic conjunctivitis can be viral, bacterial, or chlamydial in origin. It can be unilateral or bilateral with stinging or burning rather than itching and often with a foreign body sensation. Ocular discharge can be watery, mucoid, or purulent. Masqueraders of ocular allergy also include nasolacrimal duct obstruction, foreign body, blepharoconjunctivitis, dry eye, uveitis, and trauma.

Treatment.

Primary treatment of ocular allergies includes avoidance of allergens, cold compresses, and lubrication. Secondary treatment regimens include the use of oral or topical antihistamines, topical decongestants, mast cell stabilizers, and

anti-inflammatory agents (Table 141–1). Children often complain of stinging or burning with use of topical ophthalmic preparations and usually prefer oral antihistamines for allergic conjunctivitis. Using refrigerated medications may decrease some of the discomfort associated with their use. Topical decongestants act as vasoconstrictors, reducing erythema, vascular congestion, and eyelid edema, but do not diminish the allergic response. Adverse effects of topical vasoconstrictors include burning or stinging and rebound hyperemia or conjunctivitis medicamentosa with chronic use. Combined use of an antihistamine and a vasoconstrictive agent is more effective than use of either agent alone. Tertiary treatment of ocular allergy includes topical, or rarely oral, corticosteroids. Local administration of topical corticosteroids may be associated with increased intraocular pressure, viral infections, and cataract formation. Allergen immunotherapy can be very effective in seasonal and perennial allergic conjunctivitis, especially when associated with rhinitis. It can decrease the need for oral or topical medications to control allergy symptoms.

TABLE 141-1 -- **Topical Ophthalmic Medications for Allergic Conjunctivitis**

Medications	**Daily Dosing**
Antihistamines	
Levocabastine hydrochloride (Livostin) 0.05%	1 gtt bid-qid
Emedastine difumarate (Emadine) 0.05%	1 gtt qid
Azelastine hydrochloride (Optivar) 0.05%	1 gtt bid
Antihistamine-vasoconstrictor combinations	
Pheniramine maleate 0.3%/naphazoline hydrochloride 0.025% (Naphcon-A)	1–2 gtt qid
Mast cell stabilizers	
Cromolyn sodium (Opticrom) 4%	1–2 gtt q4–6hr
Lodoxamide tromethamine (Alomide) 0.1%	1–2 gtt qid
Nedocromil sodium (Alocril) 2%	1–2 gtt bid
Pemirolast potassium (Alamast) 0.1%	1–2 gtt qid
Antihistamine/mast cell stabilizers	
Olopatadine hydrochloride (Patanol) 0.1%	1 gtt bid (8 hr apart)
Ketotifen fumarate (Zaditor) 0.025%	1 gtt bid q8–12hr
Nonsteroidal anti-inflammatory drugs	
Ketorolac tromethamine (Acular, Acular Preservative-Free) 0.5%	1 gtt qid

Chapter 142 - Adverse Reactions to Foods

Hugh A. Sampson
Donald Y. M. Leung

Adverse reactions to foods consist of any untoward reaction after the ingestion of a food or food additive. These reactions are classically divided into **food intolerances,** which are adverse physiologic responses, or **food hypersensitivities,** which are allergies and adverse immunologic responses (Box 142–1). Like other atopic disorders, food allergies have increased over the past 3 decades, primarily in "Westernized" countries, and now affect an estimated 2% of the U.S. population. Up to 6% of infants and young children experience food allergic reactions in the first 3 yr of life; studies from a number of Westernized countries indicate that about 2.5% of infants develop cow's milk allergy, 1.5% develop egg allergy, and 0.6% develop peanut allergy in the first few years of life. Most infants and young children "outgrow" milk and egg allergy, with about one half outgrowing their allergy within 2–3 yr. In contrast, about 80% of those with peanut, nut, or seafood allergy will retain their allergy for life.

Etiology.

Adverse food reactions may be the result of intolerances due to functional properties of foods or physiologic responses of the host or of hypersensitivities from adverse immunologic responses of the host (see Box 142–1). Although food represents the largest antigenic load confronting the body, the gut-associated lymphoid tissue (GALT) is able to readily discriminate between "harmless" foods and pathogenic organisms. Ingestion of food leads to **oral tolerance,** or the induction of T-cell anergy and T regulatory cells that enable the systemic immune system to "ignore" the roughly 2% of antigenic protein normally entering the systemic circulation at each meal. In young infants, functional barriers (e.g., stomach acidity, intestinal enzymes, glycocalyx) and immunologic barriers (e.g., secretory IgA) are immature and allow increased penetration of food antigens, and the GALT appears less capable of "tolerizing" compared with the mature system. Consequently, food hypersensitivity reactions most commonly develop during this susceptible age.

Pathogenesis.

Food intolerances are the result of a variety of mechanisms, whereas food hypersensitivities are predominantly due to IgE-mediated and/or cell-mediated mechanisms. In susceptible individuals exposed to certain allergens, food-specific IgE antibodies are formed that bind to Fcε receptors on mast cells, basophils, macrophages, and dendritic cells. When food allergens penetrate mucosal barriers and reach cell-bound IgE antibodies, mediators are released that induce vasodilatation, smooth muscle contraction, and mucus secretion, which results in symptoms of immediate hypersensitivity. Activated mast cells and macrophages may release a number of cytokines that attract

Box 142-1. Adverse Food Reactions

FOOD INTOLERANCE

Host Factors

Enzyme deficiencies–lactase (primary or secondary), fructase (maturational delay)

Gastrointestinal disorders–inflammatory bowel disease, irritable bowel syndrome

Idiosyncratic reactions–caffeine in soft drinks ("hyperactivity")

Psychologic–food phobias

Migraines (rare)

Food Factors

Infectious organisms–*Escherichia coli*, *Staphylococcus aureus*, *Clostridium*

Toxins–histamine (scombroid poisoning), saxitoxin (shellfish)

Pharmacologic agents–caffeine, theobromine (chocolate, tea), tryptamine (tomatoes), tyramine (cheese)

Pharmacologic agents–caffeine, theobromine (chocolate, tea), tryptamine (tomatoes), tyramine (cheese)

Contaminants–heavy metals, pesticides, antibiotics

FOOD HYPERSENSITIVITIES

IgE Mediated

Cutaneous–urticaria, angioedema, morbilliform rashes and flushing

Gastrointestinal–oral allergy syndrome, gastrointestinal anaphylaxis

Respiratory–acute rhinoconjunctivitis, bronchospasm (wheezing)

Generalized–anaphylactic shock

Mixed IgE and Cell Mediated

Cutaneous–atopic dermatitis

Gastrointestinal–allergic eosinophilic esophagitis and gastroenteritis

Respiratory–asthma

Cell Mediated

Cutaneous–contact dermatitis, dermatitis herpetiformis

Gastrointestinal–food protein–induced enterocolitis, proctocolitis, and enteropathy syndromes, celiac disease

Respiratory–food-induced pulmonary hemosiderosis (Heiner syndrome)

Unclassified

Cow's milk–induced anemia

Unclassified

Cow's milk–induced anemia

and activate other cells, such as eosinophils and lymphocytes, leading to inflammation that is more prolonged. Symptoms elicited during acute IgE-mediated reactions can affect the skin (urticaria, angioedema, and flushing), gastrointestinal tract (oral pruritus and angioedema, nausea, abdominal pain, vomiting, and diarrhea), respiratory tract (nasal congestion, rhinorrhea, pruritus and sneezing, laryngeal edema, and dyspnea, shortness of breath and wheezing), and cardiovascular system (dysrhythmias, hypotension, and loss of consciousness). In the other major form of food hypersensitivities, lymphocytes, primarily food allergen–specific T cells, secrete excessive amounts of various cytokines that lead to a “delayed” inflammatory process affecting the skin (pruritus and erythematous rash), gastrointestinal tract (cachexia, early satiety, abdominal pain, vomiting, and diarrhea) or respiratory tract (food-induced pulmonary hemosiderosis). Mixed IgE and cellular responses to food allergens can also lead to chronic disorders such as atopic dermatitis, asthma, and allergic eosinophilic gastroenteritis.

Children developing IgE-mediated food allergies may be sensitized by food allergens penetrating the gastrointestinal barrier, **class 1 food allergens,** or by partially homologous allergens, such as plant pollens, penetrating the respiratory tract, **class 2 food allergens.** Any food may cause class 1 food allergies, but egg, milk, peanuts, nuts, fish, soy, and wheat account for about 90% of food allergy up to the teenage years. Many of the major allergenic proteins of these foods have been characterized (Table 142–1). Exposure and sensitization to these proteins often occur very early in life, because intact food proteins are passed to the infant through maternal breast milk and, after introduction of solid foods, many parents strive to provide their infant with a

TABLE 142-1 -- **Major Food Allergens**

Class 1		
Food	***Protein***	***Allergen Name***
Cow's milk	Casein	Bos d8

		Cantaloupe
		Honeydew

highly varied diet. Virtually all milk allergy develops by 12 mo of age and all egg allergy by 18 mo of age, and the median age of first peanut allergic reactions is 14 mo. Class 2 allergens are typically plant or fruit proteins that are partially homologous to pollen proteins (see Table 142–1). With the development of seasonal allergic rhinitis, from birch, grass, or ragweed pollens, ingestion of certain uncooked fruits or vegetables provoke the oral allergy syndrome. Intermittent ingestion of allergenic foods will lead to acute symptoms, whereas prolonged exposure may lead to chronic disorders such as atopic dermatitis and asthma. Cell-mediated sensitivity typically develops to class 1 allergens.

Clinical Manifestations.

From a clinical and diagnostic standpoint, it is most useful to subdivide food hypersensitivity disorders by the target organ predominantly affected and immune mechanism (see Box 142–1).

GASTROINTESTINAL MANIFESTATIONS.

Gastrointestinal food allergies are often the first form of allergy to affect infants and young children and typically present as irritability, vomiting or "spitting-up," diarrhea, and poor weight gain. Cell-mediated hypersensitivities predominate, making standard allergy tests such as prick skin tests and RAST tests of little diagnostic value.

Food protein–induced enterocolitis syndrome typically presents in the first several months of life with irritability, protracted vomiting, and diarrhea, not infrequently resulting in dehydration. Vomiting generally occurs 1–3?hr after feeding, and continued exposure may result in bloody diarrhea, anemia, abdominal distention, and failure to thrive. Symptoms are most commonly provoked by cow's milk or soy protein–based formulas but occasionally result from food proteins passed in maternal breast milk. A similar enterocolitis syndrome has been reported in older infants and children from egg, wheat, rice, oat, peanut, nuts, chicken, turkey, and fish sensitivity. Hypotension occurs in about 15% of cases after allergen ingestion.

Food protein–induced proctocolitis presents in the first few months of life as blood-streaked stools in otherwise healthy looking infants. About 60% of cases occur in breast-fed infants, with the remainder largely in infants fed cow's milk– or soy protein–based formula. Blood loss is typically modest but occasionally can produce anemia.

Food protein–induced enteropathy often presents in the first several months of life with diarrhea, not infrequently steatorrhea, and poor weight gain. Symptoms include protracted diarrhea, vomiting in up to two thirds of cases, failure to thrive, abdominal distention, early satiety, and malabsorption. Anemia,

edema, and hypoproteinemia occur occasionally. **Cow's milk sensitivity** is the most frequent cause of this syndrome in young infants, but it also has been associated with sensitivity to soy, egg, wheat, rice, chicken, and fish in older children. **Celiac disease** is the most severe form of enteropathy, characterized by a more extensive loss of absorptive villi and hyperplasia of the crypts leading to malabsorption, chronic diarrhea, steatorrhea, abdominal distention, flatulence, and weight loss or failure to thrive. Oral ulcers and other extraintestinal symptoms secondary to malabsorption are not uncommon. Genetically susceptible individuals (HLA-DQ2 or DQ8) develop a cell- mediated response to tissue transglutaminase (tTGase) deamidated gliadin found in wheat, oat, rye, and barley.

Allergic eosinophilic esophagitis may present from infancy through adolescence. In young children, it is primarily cell-mediated and presents as chronic gastroesophageal reflux (GER), intermittent emesis, food refusal, abdominal pain, dysphagia, irritability, sleep disturbance, and failure to respond to conventional reflux medications. A study of children younger than 1 yr of age presenting with GER found that 40% had cow's milk–induced reflux. **Allergic eosinophilic gastroenteritis** occurs at any age and presents as symptoms similar to esophagitis as well as prominent weight loss or failure to thrive, which are the hallmarks of this disorder. Up to 50% of patients are atopic, and food-induced IgE-mediated reactions have been implicated in a minority of patients. Generalized edema secondary to hypoalbuminemia may occur in some infants with marked protein-losing enteropathy.

Oral allergy syndrome is an IgE-mediated hypersensitivity that occurs in many older children with birch pollen and ragweed-induced allergic rhinitis. Symptoms are usually confined to the oropharynx and consist of the rapid onset of pruritus, tingling, and angioedema of the lips, tongue, palate, and throat, and occasionally a sensation of pruritus in the ears and/or tightness in the throat. Symptoms are generally short-lived and are due to local mast cell activation by fresh fruit and vegetable proteins that cross react with birch pollen (apple, carrot, potato, celery, hazel nuts, and kiwi) and ragweed pollen (banana and melons—watermelon, cantaloupe, etc.).

Gastrointestinal anaphylaxis generally presents as acute abdominal pain and vomiting that accompany other IgE-mediated allergic symptoms.

SKIN MANIFESTATIONS.

Cutaneous food allergies are also common in infants and young children.

Atopic dermatitis is a form of eczema that generally begins in early infancy and is

characterized by pruritus, chronically relapsing course, and association with asthma and allergic rhinitis (see Chapter 135). Although not often apparent by history, at least one third of children with moderate to severe atopic dermatitis have food allergies. The younger the child and the more severe the eczema, the more likely food allergy is playing a pathogenic role in the disorder.

Acute urticaria and angioedema are among the most common symptoms of food allergic reactions (see Chapter 136). Onset of symptoms may be very rapid, following within minutes of ingesting the responsible allergen. Symptoms are due to activation of IgE-bearing mast cells by circulating food allergens, which are absorbed and circulated rapidly throughout the body. Foods most commonly incriminated in children include egg, milk, peanuts, and nuts, although reactions to various seeds (e.g., sesame, poppy) and fruits (e.g., kiwi) are becoming more common. **Chronic urticaria and angioedema** are rarely due to food allergies.

RESPIRATORY MANIFESTATIONS.

Respiratory food allergies are uncommon as isolated symptoms. Although many parents believe that nasal congestion in infants is often due to milk allergy, a number of studies showed this not to be the case. **Food-induced rhinoconjunctivitis** symptoms typically accompany allergic symptoms in other target organs, such as skin, and consist of typical allergic rhinitis symptoms (periocular pruritus and tearing, nasal congestion and pruritus, sneezing, and rhinorrhea). Wheezing occurs in about 25% of IgE-mediated food allergic reactions, but only 5–10% of asthmatic patients have food-induced respiratory symptoms.

Food allergic reactions are the single most common cause of anaphylaxis seen in hospital emergency departments. In addition to the rapid onset of cutaneous, respiratory, and gastrointestinal symptoms, patients may develop cardiovascular symptoms including hypotension, vascular collapse, and cardiac dysrhythmias, presumably caused by massive mast cell mediator release. **Food-associated exercise-induced anaphylaxis** is occurring more frequently among teenage athletes, especially females (see Chapter 137).

Diagnosis.

A thorough medical history is necessary to differentiate whether a patient's symptomatology represents an adverse reaction (Box 142–2), if the adverse food reaction is an intolerance or hypersensitivity reaction, and if the latter, whether it is likely to be an IgE-mediated or a cell-mediated response. The following facts should be established: (1) the food suspected of provoking the reaction and the quantity ingested, (2) the time interval between ingestion and the development of symptoms, (3) the type of symptoms elicited by the ingestion, (4) whether ingesting the suspected food produced similar symptoms on other occasions, (5) whether other inciting factors, such as exercise, are necessary, and (6) the time interval from the last reaction to the food. Prick skin tests and radioallergosorbent tests are useful for demonstrating IgE sensitization. Many fruits and vegetables require testing with fresh produce because labile proteins are destroyed during commercial preparation. A negative skin test virtually excludes an IgE-mediated form of food allergy. Conversely, the majority of children with positive skin tests to a food will not react when the food is ingested, so more definitive tests, such as quantitative IgE levels or food elimination and challenge, are often necessary to establish a diagnosis of food allergy. Serum food-specific IgE levels = 15?kU_a /L for milk, = 7?kU_a /L for egg, and = 14?kU_a /L for peanut are associated with a >95% likelihood of clinical reactivity to these foods. In the absence of a clear history of reactivity to a food

Box 142-2. Differential Diagnosis of Adverse Food Reactions

GASTROINTESTINAL DISORDERS (WITH VOMITING AND/OR DIARRHEA)

- Structural abnormalities (pyloric stenosis, Hirschsprung disease)
- Enzyme deficiencies (primary or secondary)
  - Disaccharidase deficiency–lactase, fructase, sucrase-isomaltase
  - Galactosemia
- Malignancy with obstruction
- Other: pancreatic insufficiency (cystic fibrosis), peptic disease

CONTAMINANTS AND ADDITIVES

- Flavorings and preservatives–rarely cause symptoms
  - Sodium metabisulfite, monosodium glutamate, nitrites
- Dyes and colorings–very rarely cause symptoms [urticaria, eczema]
  - Tartrazine
- Toxins
  - Bacterial, fungal (aflatoxin), fish related (scombroid, ciguatera)
- Infectious organisms

Toxins

Bacterial, fungal (aflatoxin), fish related (scombroid, ciguatera)

Infectious organisms

Bacteria (*Salmonella*, *Escherichia coli*, *Shigella*)

Virus (rotavirus, enterovirus)

Parasites (*Giardia*, *Akis simplex* [in fish])

Accidental contaminants

Heavy metals, pesticides

Pharmacologic agents

Caffeine, glycosidal alkaloid solanine (potato spuds), histamine (fish), serotonin (banana, tomato), tryptamine (tomato), tyramine (cheese)

PSYCHOLOGIC REACTIONS

Food phobias

and evidence of food-specific IgE antibodies, definitive studies must be performed before recommending avoidance or the use of highly restrictive diets that may be nutritionally deficient, logistically impractical, and disruptive to the family and the source of future feeding disorders. IgE-mediated food allergic reactions are generally very food specific, so the use of broad exclusionary diets, such as avoidance of all legumes, cereal grains, and animal products, is not warranted. Unfortunately, there are no laboratory studies that help identify foods responsible for cell-mediated reactions. Consequently, elimination diets followed by food challenges are the only way to establish the diagnosis. Allergists experienced in dealing with food allergic reactions and able to treat anaphylaxis should perform **food challenges.** Before initiating a food challenge, the suspected food should be eliminated from the diet for 10–14 days for IgE-mediated food allergy and up to 8 wk for some cell-mediated disorders, such as allergic eosinophilic gastroenteritis. Many children with cell-mediated reactions to cow's milk will not tolerate hydrolysate formulas and must be placed on amino acid–derived products (e.g., ELECARE or Neocate). If symptoms remain unchanged and appropriate elimination diets have been utilized, it is unlikely that food allergy is responsible for the child's disorder.

Treatment.

Appropriate identification and elimination of foods responsible for food hypersensitivity reactions are the only validated treatments for food allergies. Complete elimination of common foods (e.g., soy, egg, wheat, rice, chicken, fish, peanut, and nuts) is very difficult, owing to their widespread use in a variety of processed food. The Food Allergy and Anaphylaxis Network (www.foodallergy.org or 800-929-4040) provides excellent information to help parents deal with both the practical and emotional issues surrounding these diets. Children with asthma and IgE-mediated food allergy should be given self-injectable epinephrine and a written emergency plan in case of accidental ingestion (see Chapter 137). Because many food allergies are outgrown, arrangements should be made to have children periodically re-evaluated by an allergist to determine whether they have lost their clinical reactivity. New forms of immunotherapy and use of anti-IgE therapy are under study and may provide definitive means of treating food allergies in future years.

Prevention.

There is no consensus as to whether food allergies can be prevented. However, several authorities recommend delaying introduction of major food allergens to infants from atopic families. Recommendations include promotion of breast-feeding with maternal exclusion of peanut and nut products from the mother's diet and delay in introducing major allergenic foods: cow's milk until 1 yr of age; egg until 18–24 mo of age, and peanut, tree nuts, and seafood until 3 yr of age.

Part 15 - Rheumatic Diseases of Childhood (Connective Tissue Diseases, Collagen Vascular Diseases)

Chapter 143 - Evaluation of Suspected Rheumatic Disease

Michael L. Miller

Rheumatic diseases result from abnormally regulated immune responses that lead to inflammation of target organs. Because many different organs may be affected, rheumatic diseases must be considered for a wide range of presenting complaints. Often, nonrheumatic diseases that can cause similar symptoms need to be excluded during evaluation.

Early diagnosis of rheumatic disease may not always be possible because diagnostic manifestations can take time to develop. Specific diagnostic criteria for rheumatic diseases may not be met for months or, rarely, even years. During that time the clinical evaluation may need to be repeated, and occasionally, a diagnosis will need to be reconsidered. For example, a child meeting diagnostic criteria for juvenile rheumatoid arthritis (JRA) may, after several years, develop anemia, diarrhea, and small bowel biopsy findings more consistent with inflammatory bowel disease. Some patients with JRA, particularly those presenting with high titers of antinuclear antibodies (ANAs), may develop systemic lupus erythematosus (SLE) years after initial presentation. A child with polyarticular arthritis who later develops weakness disproportionate to synovitis may be diagnosed with an inflammatory myositis, such as juvenile dermatomyositis.

Etiology and Pathogenesis.

Rheumatic diseases are characterized by autoimmune effects that exaggerate the desired immune response. Normally, the immune system reacts to viruses, bacteria, and other non-self molecules but does not mount a reaction to molecules found in the host's own tissues. This **tolerance** to self is lost in rheumatic diseases. Two possible reasons, which are not mutually exclusive, for self-reactivity are (1) similarity between foreign and self molecules as recognized by immune cells, particularly T lymphocytes, and (2) viral infections with exaggerated immune responses that are otherwise suppressed. The relative contributions of these mechanisms to the pathogenesis of rheumatic diseases are still being investigated. Some genetic factors, such as specific HLA alleles, may influence susceptibility to developing disease, whereas others, such as those that influence levels of baseline immune activities, may affect disease severity.

A series of abnormal cellular and molecular events is present in many rheumatic diseases. T lymphocytes bearing T-cell receptors recognize viruses and other foreign antigens that are bound to surfaces of other cells. After the T-cell receptor binds to antigenic molecules resting in the groove of the HLA molecule, molecular signals are released that activate other cells, such as macrophages. Macrophages produce inflammatory cytokines, including tumor necrosis factor-a (TNFa), interleukin-1 (IL-1), and IL-6. These cytokines can cause tissue damage through direct effects and by attracting additional inflammatory cells to the affected site. Further damage is mediated by B lymphocytes, which are activated by helper T cells to produce excessive antibody, including autoantibodies that bind to self-antigens. The resulting complement fixation can lead to the tissue destruction that is seen with some rheumatic diseases. Normal cells in target organs can be destroyed through cytolysis that is mediated by complement, direct or indirect effects of TNFa, or effects of natural killer or cytolytic T lymphocytes.

In children with rheumatic diseases, products of the immune system may affect function of other organs. For example, IL-6 and other cytokines can bind to neuronal receptors in the central nervous system, causing fever. IL-6 can also interfere with osteoblastic activity, resulting in osteopenia, which is reflected by decreased serum osteocalcin levels. Molecules produced outside the immune system may, in turn, have an effect on immune responses. During a normal immune response, cytokines appear to induce neuroendocrine pathways to produce cortisol, which suppresses cellular and humoral activity. It is possible that defects in these pathways amplify autoimmune responses. The increased incidence of some rheumatic diseases in females may be attributable to the capability of female sex hormones to augment cellular immune responses.

Clinical Manifestations.

The history can help distinguish rheumatic conditions from other diseases. For example, parents of children with school phobias are often dubious about the prospect of returning their children to school. In contrast, parents of children with rheumatic diseases, more upset with the school absences themselves, usually are anxious to see their children return to school.

Some symptoms and signs, although not specific, may suggest rheumatic diseases (Table 143–1). Morning stiffness may be reported by children with JRA or postinfectious arthritis. Facial rashes in children with joint complaints or weakness raise the possibility of lupus or dermatomyositis. Raynaud phenomenon can be a presenting complaint of children with scleroderma and overlapping rheumatic syndromes. A history of trauma with monoarticular arthritis near the site of trauma suggests nonrheumatic disease, such as a torn meniscus or osteochondritis. A history of travel, enteric illness in the family, or exposure to sick pets suggests reactive arthritis following an enteric infection. Tick exposure in a child with joint symptoms raises the possibility of Lyme arthritis. Weakness can be present in muscular dystrophies, postviral illnesses, and inflammatory myopathies, of which juvenile dermatomyositis is the most common. Fevers are commonly seen in children with rheumatic diseases; spiking fevers returning to baseline are seen in systemic JRA. However, fever is not specific for rheumatic diseases, and evaluation for infections or malignancies may be necessary. Gait problems are found in children with orthopedic problems, such as Legg-Calvé-Perthes disease, as well as JRA. The inability to walk raises the need for immediate attention to exclude conditions such as osteomyelitis or malignancy.

Physical Examination.

The physical examination helps identify the organs involved. Because rheumatic diseases may take time

TABLE 143-1 -- **Symptoms Suggestive of Rheumatic Diseases**

Symptom	Rheumatic Diseases	Some Possible Nonrheumatic Diseases Causing Similar Symptoms
Fevers	Systemic juvenile rheumatoid arthritis	Malignancies, infections, inflammatory bowel disease
Arthralgia	Juvenile rheumatoid arthritis, systemic lupus erythematosus, juvenile dermatomyositis, scleroderma	Hypothyroidism, trauma, reactive arthritis, infections
Weakness	Juvenile dermatomyositis	Muscular dystrophies
Malar rash	Systemic lupus erythematosus	Photosensitive dermatitis
Chest pain	Juvenile rheumatoid arthritis, systemic lupus erythematosus (with associated pericarditis or costochondritis)	Costochondritis (isolated), rib fracture, spondylolysis, spondylolisthesis
Back pain	Juvenile rheumatoid arthritis, spondyloarthropathy	Vertebral microfracture, diskitis, intraspinal tumor

to evolve, repeated examinations are often important in detecting new

manifestations. The general appearance may suggest certain diagnoses. A depressed or anxious affect may suggest psychiatric disease. Lack of normal movement on the examination table may be a result of muscle weakness, arthritis, central nervous system disease, or skeletal abnormality. Weight loss or decreased weight gain may reflect malnutrition from inflammatory bowel disease. Tachycardia is seen in the child with fevers of any cause or with carditis or pericarditis. **Nailfold capillaroscopy** can detect vasculopathy, reflecting vessel injury in dermatomyositis, scleroderma, and other rheumatic diseases (see Fig. 149–3).

Apparently isolated findings may be clues to target organ involvement in rheumatic diseases. For example, a pericardial friction rub with orthopnea can be seen in pericarditis from lupus or systemic JRA. Persisting oral mucosal lesions are found in lupus; other mucous membrane involvement, such as swollen tongue or lips, raises the possibility of nonrheumatic diseases, including Kawasaki disease, Stevens-Johnson syndrome, and scarlet fever. The eye can be a target in lupus, in which episcleritis may be seen, and in JRA, in which posterior synechiae are a later complication of uveitis. Although persisting joint complaints suggest JRA, other rheumatic diseases, including lupus and dermatomyositis, can also present with arthritis. All children with joint symptoms should be asked about muscle weakness, which is seen in dermatomyositis and mixed connective tissue disease.

The joint examination can detect arthritis, which can be infectious, rheumatic, or secondary to trauma. **Arthritis** is evident by either swelling of the joint or the combination of pain and limited motion. **Arthralgia,** or pain in a joint with full range of motion, can be seen in trauma, psychogenic arthralgia, or early rheumatic disease that cannot yet be specifically diagnosed. The neurologic examination can identify focal deficits resulting from intracranial or intraspinal lesions as well as muscle weakness, which is seen in many diseases including postviral syndromes, inflammatory myositis, other rheumatic diseases, and muscular dystrophies.

Erythema nodosum, a rash characterized by pretibial tender erythematous nodules found in the deep dermis and subcutaneous tissue (Fig. 143–1), is a hypersensitivity reaction resulting from certain infections, inflammatory diseases, or drugs. The finding of erythema nodosum should lead to consideration of possible underlying causes. Common infectious triggers include group A *Streptococcus* pharyngitis, tuberculosis, *Yersinia*, histoplasmosis, and coccidioidomycosis. Erythema nodosum is sometimes the first manifestation of inflammatory bowel disease, sarcoidosis, or spondyloarthropathy. The rash may also develop after exposure to sulfonamides, phenytoin, or oral contraceptive agents. Lesions may evolve from erythematous to bluish, may sometimes be flat, and in severe cases may be found along the entire length of the legs or even involve the arms. New crops of nodules may develop over several weeks and are sometimes accompanied by fever. Although erythema nodosum is itself a self-limited condition that responds to treatment of the underlying etiology, it must be distinguished from cellulitis, insect bites, thrombophlebitis, and fungal skin infections. When necessary to alleviate pain, supportive treatment includes bed rest, elevation of the legs, and analgesic medication.

Laboratory Findings.

The erythrocyte sedimentation rate (ESR) is useful to screen for infectious and rheumatic diseases. However, a normal value does not exclude rheumatic diseases. Although transient infections can increase the ESR, elevated values persisting for more than several weeks require explanation, and extensive evaluation may be necessary. Usually the symptoms, physical findings, or other laboratory abnormalities will guide the focus of further evaluation.

Figure 143-1 Erythematous nodules and plaques are present over both shins. The skin overlying the lesions is red, smooth, and shiny. The nodules are usually tender. Erythema nodosum is considered a hypersensitivity reaction and can be associated with a variety of diseases, including sarcoidosis, group *A Streptococcus* infection, tuberculosis, coccidioidomycosis, and ulcerative colitis. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases; Copyright 1991, 1995, 1997. Used by permission of the American College of Rheumatology.)

The **ANA test** is a screening test for specific antibodies against nuclear constituents, some of which have been characterized (Table 143–2). A positive ANA antibody titer (=1:80) is a nonspecific reflection of increased lymphocyte activity. Positive ANA tests are found in children with rheumatic diseases and other diseases such as idiopathic thrombocytopenic purpura, Crohn disease, chronic autoimmune hepatitis, Graves disease, and, rarely, leukemia or lymphoma. Children with positive ANA tests who have nonrheumatic diseases may sometimes develop overlapping rheumatic syndromes, such as lupus. In such cases, other laboratory findings typically appear (e.g., antibodies to DNA in lupus patients). Some drugs, such as anticonvulsant medications (e.g., phenytoin, ethosuximide) and antiarrhythmic agents (e.g., procainamide) can cause positive ANA tests, usually without rheumatic disease. Occasionally, lupus develops in such patients. Malaria and some parasitic infections can also cause positive ANA tests.

Some children with positive ANA tests but no persisting symptoms have normal physical examinations and lack other remarkable laboratory findings. Such children rarely develop a rheumatic disease. Other children with positive ANA tests have been found to have arthralgia related to hyperextensible joints; the reason for the association is unknown. These children need to be distinguished from those who develop JRA or other rheumatic disease, which is best detected by periodic re-evaluation to detect changes in physical findings or laboratory abnormalities (e.g., anemia, thrombocytopenia, nephritis).

Other immunologic laboratory tests, although not diagnostic of rheumatic disease, are useful in characterizing the extent of immune activation and in monitoring response to therapy. For example, levels of total hemolytic complement (CH_{50}), C3, and C4 may be decreased in active lupus or vasculitis syndromes. Immune activation may be reflected by elevated levels of immune complexes, serum immunoglobulins, neopterin (a macrophage product), and von Willebrand factor antigen (a molecule found on the surface of vascular endothelium).

Other laboratory results may suggest a nonrheumatic diagnosis. A decrease in two of the three blood cell lines (e.g., leukopenia, anemia, or thrombocytopenia) in a child with limb pain may be seen in acute lymphocytic leukemia. Lactate dehydrogenase levels may be elevated in rheumatic diseases as a result of cell turnover; marked

elevations raise the possibility of malignancy. Thyroid function studies can exclude hypothyroidism, which may cause musculoskeletal symptoms. Decreased albumin and serum protein may be seen in nephrosis or inflammatory bowel disease.

Imaging studies also contribute to the evaluation. Bone scans or MRI can detect early osteomyelitis or malignancies. MRI studies with gadolinium for joint evaluation and T2

TABLE 143-2 -- **Specific Antinuclear Antibodies and Associated Diseases**

Antigen	Disease
Histone	Drug-induced lupus
Ribonucleoprotein	Mixed connective tissue disease
Pm-Scl	Sclerodermatomyositis
Scl	Scleroderma
Sm	Systemic lupus erythematosus
Ro/SSA	Sjögren syndrome, congenital heart block, annular erythema
La/SSB	Sjögren syndrome

The ANA test is a screening test; it does not determine which of various known and unknown nuclear antigens the antinuclear antibody is specific for.Nonspecific elevated ANAs may be detected in healthy children (usually at low titer) and in those with various rheumatic and nonrheumatic diseases. The above specific ANAs are typically found with the corresponding diseases; however, they may sometimes be found in patients without manifestations suggestive of (or diagnostic for) these conditions.

weighted fat suppression for muscle evaluation can reveal tissue abnormalities seen in such diseases as JRA, dermatomyositis, and sarcoidosis. Findings from MRI studies may also suggest nonrheumatic diseases. Echocardiography can distinguish patients with rheumatic carditis from those with Kawasaki disease or pericarditis resulting from systemic lupus erythematosus or systemic JRA. **REFERENCES**

Chapter 144 - Treatment of Rheumatic Diseases

Daniel J. Lovell
Michael L. Miller
James T. Cassidy

Treatment of children with rheumatic diseases is complex and challenging. The efforts of a team of health care professionals need to be melded into a coordinated system of management that is individualized to meet the needs of each patient and that is sensitive to the capabilities and psychosocial resources of the family. In addition, courses of the rheumatic diseases are not static. For each child, the disease manifestations can vary in severity over time and treatment needs to be adjusted accordingly. The therapeutic program must provide appropriate therapy for currently symptomatic problems, such as arthritis, as well as include appropriate screening methods for often clinically silent problems such as uveitis in patients with juvenile rheumatoid arthritis (JRA) and early nephritis in patients with systemic lupus erythematosus (SLE). The treatment regimen should not focus only on the child with the rheumatic disease. When rheumatic disease occurs in a child, all family members are affected. Indeed, studies have indicated that siblings of a child with a rheumatic disease are often more adversely affected psychosocially than the patient. Furthermore, family dynamics have a significant impact on treatment and outcome. Several studies have documented that the emotional status of the parents at the time of diagnosis of rheumatic disease in their child is one of the strongest predictors of outcome 5–10 yr later. Despite this complex and

ever-changing therapeutic milieu, current approaches to management supervised by a multidisciplinary team (Table 144–1) experienced in the care of children with rheumatic diseases usually result in acceptable clinical outcomes.

The childhood rheumatic diseases are neither benign nor short-lived in the majority of patients. Optimal treatment for these children requires the coordinated efforts of various health care professionals expert in this highly specialized area. The treatment program includes physical and psychosocial interventions, as well as medications, and requires tailoring to the needs and severity of each particular child's illness that will vary over time. Current therapies are not curative, as evidenced by the chronicity of these diseases.

Pediatric Rheumatology Teams and Primary Care Physicians.

The goals for treatment are to maximize the daily functional activities of affected children, relieve discomfort, prevent or reduce organ damage, and avoid or minimize drug toxicity. Although medical therapy is important, nondrug therapy assumes a large role in the treatment of rheumatic diseases. The role of the physician responsible for treating a child with a rheumatic disease includes, in addition to prescribing and monitoring medications, coordinating the efforts of the other team members and educating the child and family about treatments and the nature and expected course of the disease. A key predictor of long-term outcome is early referral to a rheumatology team experienced in the care of children with rheumatic diseases. For example, significant differences in outcome in patients with JRA even 10 yr after disease onset were evident in those patients referred to a pediatric rheumatology center within 6 mo after disease onset compared with those with referral more than 6 mo after disease onset.

The pediatric rheumatology team offers coordinated services for these children and their families. By working closely with the team, the primary care physician helps monitor compliance with treatment plans, check for adverse effects of the medical therapy, evaluate symptoms of intercurrent illnesses, and exclude disease exacerbation or concomitant infections. Communicating with subspecialists and teams at tertiary care centers allows intervention when poor compliance occurs and symptoms flare.

Each member of the pediatric rheumatology team contributes individually and cooperatively to the child's care (Table 144–2). The pediatric rheumatologist establishes the diagnosis, assesses response to treatment, and monitors for changes in disease manifestations. With assistance from other team members, this leader of the team also monitors the child's psychosocial status, including such areas as pain, emotional and behavioral responses to disease, change in roles at home and school, and family response to the child's illness. The nurse provides education about specific chronic illnesses and correct administration of medication. Occupational and physical therapists assess limitations in joint movement and physical function and provide plans for long-term rehabilitation programs. Physical and occupational therapists prescribe and monitor exercise and splinting programs that families perform at home with the child

to improve or maintain joint motion in children with arthritis, as well as in patients with myositis to avoid muscle contractures and improve muscle strength. Splints are used to lessen unnecessary mechanical stress on joints that is often associated with routine daily tasks. Splints may also improve muscle or joint contractures and avoid joint deformities, such as subluxation of the wrist. Ophthalmologists should examine children with JRA on a regular basis to screen for uveitis (every 3–12 mo, depending on the type of JRA) and to assess for ocular toxicity from certain medications (every 6–12 mo) such as hydroxychloroquine or glucocorticoids. Social workers are invaluable resources to families by helping them confront the significant social and emotional stresses imposed by the illness, deal with the financial maze of insurance coverage and national and state programs, and identify community resources needed to provide support. Children with rheumatic diseases are often undernourished because of disease- or medication-related anorexia, or they are obese or overnourished as a result of glucocorticoid therapy. Early and ongoing involvement of a nutritionist can significantly improve the health of these patients.

Medications.

Medications used for treatment of childhood rheumatic diseases (see Table 144–2) have various mechanisms of action, which is unknown for some, but all share the ability to suppress inflammation. Key to satisfactory short- and long-term outcomes in these children is early induction of a significant and sustained suppression of this inflammation.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS (NSAIDS).

A large number of NSAIDs are approved by the Food and Drug Administration (FDA) for use in adults with rheumatoid arthritis, but a much smaller number are approved for use in children with JRA. NSAIDs can be prescribed to decrease acute and chronic inflammation associated with arthritis, pleuritis, pericarditis, uveitis, and some forms of vasculitis. Lower doses, typically those approved for over-the-counter use,

or intermittent dosing can result in analgesia but rarely significant anti-inflammatory effect. To reduce inflammation requires regular administration of adequate doses, on a weight (mg/kg) or body surface area (mg/m^2) basis and for longer periods than for analgesia alone. For example, the mean time to achieve an anti-inflammatory effect in the arthritis associated with JRA was

30 days of consistent administration. NSAIDs work primarily by inhibiting the enzyme **cyclooxygenase (COX),** which is critical in the production of **prostaglandins,** a family of substances that have many physiologic effects, including that of promoting inflammation. Two types of COX receptors have been demonstrated, and several NSAIDs have been approved for use in adults with rheumatoid arthritis that selectively inhibit those receptors responsible for promoting inflammation, which are **selective COX-2 inhibitors.** These selective COX-2 inhibitors have been shown in adults to have similar anti-inflammatory effects with fewer side effects than traditional NSAIDs. Clinical studies of the selective COX-2 inhibitors are in progress in children with JRA.

The most frequent adverse effects with NSAIDs in children are nausea, decreased appetite, and abdominal pain. Gastritis or gastric or duodenal ulceration occurs less frequently in children than in adults. In addition, each of the following side effects occurs in 5% or less of children on long-term NSAID therapy: central nervous system (CNS) symptoms (e.g., mood change, difficulty concentrating that can simulate attention deficit disorder [ADD], sleepiness, irritability, headache, tinnitus), alopecia, anemia, elevated liver enzymes, proteinuria, and hematuria. These NSAID-associated side effects reverse quickly once the medication is stopped. Several NSAID-specific adverse reactions may also occur. Ibuprofen can induce aseptic meningitis in some patients with SLE and rarely in patients with JRA. Naproxen is far more likely in children than other NSAIDs to cause a unique skin reaction called **pseudoporphyria**, which is characterized by small hypopigmented flat scars occurring in areas of even minor skin trauma (skin fragility), such as fingernail scratches, or after small spontaneous blister lesions. Naproxen-induced pseudoporphyria is more likely to occur in fair-skinned individuals and in sun-exposed areas. Confirmation of this skin toxicity should prompt immediate discontinuation of naproxen, because the scars can persist for several years. NSAIDs should be used cautiously in patients with dermatomyositis or systemic vasculitis because there is an increased frequency of gastrointestinal ulceration in these disorders.

The response to NSAIDs varies greatly among individual patients, but overall, approximately 40–60% of children with JRA experience significant improvement in their arthritis. Patients often must try several different NSAIDs before finding the one that demonstrates the most clinical benefit. NSAIDs with longer half-lives or sustained-release formulations have been developed to allow for once- or twice-daily dosing. For patients with JRA or milder cases of SLE, NSAIDs are often a cornerstone of the treatment program. For approximately 20–40% of patients with JRA, NSAIDs are the only drug therapy required to control the arthritis.

METHOTREXATE.

Methotrexate has been used and studied in almost all of the rheumatic diseases and in many nonrheumatic conditions, including asthma, inflammatory bowel disease, cystic fibrosis, uveitis, and diabetes. It has a central role in the treatment of arthritis and is used in approximately 60% of patients with polyarticular JRA. Methotrexate given orally in a dose of 10?mg/m^2 once weekly was shown to be significantly better than placebo in a randomized, placebo-controlled trial (63% of methotrexate and 36% of placebo patients responded, $p < .001$). In a smaller, uncontrolled study in patients with JRA who failed to respond to the 10?mg/m^2 /wk dose, methotrexate given intramuscularly in higher doses of 23–29?mg/m^2 /wk resulted in prolonged clinical improvement in 70% of the patients. Patients with JRA who demonstrate a clinical response in articular inflammation with methotrexate also have improvement in radiologic evaluation of joint damage, growth rate, and functional ability in daily tasks. Subcutaneous administration of methotrexate has been demonstrated to have similar absorption and pharmacokinetic properties as intramuscular injection, and is much less painful for the children. Methotrexate is commonly used in treatment of juvenile dermatomyositis that has shown no or inadequate response to glucocorticoids. About 70% of patients with dermatomyositis treated with methotrexate demonstrate improvement in their myositis. It has also been successfully used in a dosage of 10–20?mg/m^2 /wk in patients with SLE to treat arthritis, serositis, and, in some cases, nephritis.

Studies in adults have indicated that the mechanism of action of methotrexate, which is an analog of folic acid, in arthritis is not primarily suppression of either folic acid metabolism or bone marrow activity. Methotrexate inhibits dihydrofolate reductase, which is important in purine synthesis, resulting in suppression of inflammation. Methotrexate is well tolerated by children. Because of the lower dose and alternative mechanisms of action, toxicity from methotrexate is much milder and qualitatively different from that observed when methotrexate is used to treat neoplastic diseases. In eight published studies that included 288 patients with JRA on methotrexate therapy, 13% of patients had gastrointestinal toxicity, 3% stomatitis, 15% elevated liver enzymes, 1–2% headache, and <1% leukopenia, interstitial pneumonitis, rash, or alopecia.

Hepatotoxicity observed among adults with rheumatoid arthritis treated with methotrexate has raised concern about similar problems occurring in children. In 46 liver biopsies performed in patients with JRA undergoing long-term methotrexate treatment, 95% of specimens were normal, 5% showed mild fibrosis, but none demonstrated even moderate liver damage. Lymphoproliferative disorders have also been reported in adults, usually after primary Epstein-Barr virus infection, and may not be directly related to the drug per se. However, given the large number of adults on methotrexate, the relative risk of lymphoproliferative disease remains low, at approximately 1.0–1.5%. Thus, methotrexate has become established as one of the cornerstone medications in pediatric rheumatology because of its potential to induce significant improvement in chronic inflammation and to maintain that improvement for long periods because of low toxicity and high patient acceptance.

GLUCOCORTICOIDS.

Glucocorticoids are given by various routes for rheumatic diseases, including oral, intravenous, ocular, and intra-articular administration. Oral glucocorticoids are a cornerstone of treatment for moderate to severe SLE, dermatomyositis, and most forms of vasculitis. However, long-term use always leads to adverse effects. Steroid therapy in these chronic diseases must be carefully supervised; a responsible plan requires steroid tapering to acceptable doses for long-term use or the introduction of other anti-inflammatory medications to serve as steroid-sparing agents. Intravenous steroid administration has been used as an alternative to oral administration to treat more severe, acute manifestations of systemic connective tissue diseases such as SLE, dermatomyositis, and vasculitis. The intravenous route allows for much higher therapeutic doses to obtain an immediate, profound anti-inflammatory effect. Methylprednisolone, 10–30?mg/kg/dose up to a maximum of 1?g, has been the intravenous drug of choice. Although generally associated with fewer adverse effects than oral steroids, intravenous administration is not without significant and occasionally life-threatening toxicities, such as cardiac arrhythmias, acute hypertension, hypotension, and shock.

Ocular steroids are prescribed under the supervision of an ophthalmologist either as drops or injections into the soft tissue surrounding the globe (sub-Tenon injection) for the uveitis associated with JRA. Long-term ocular steroid use can lead to cataract formation and glaucoma. However, current ophthalmic management has significantly decreased the frequency of blindness as a complication of JRA-associated uveitis.

Intra-articular steroids are prescribed with increasing frequency for children with JRA in whom one or several joints have not responded to standard parenteral drug therapy or as the initial therapy in patients with arthritis involving only one

or two joints. Almost all patients have significant improvement in both symptoms and physical findings within 2–3 days, which persists for at least 6 mo in 60% and for at least 12 mo in 45%. Intra-articular administration may result in subcutaneous atrophy and hypopigmentation of the skin in the area surrounding the injection site, as well as subcutaneous calcifications along the needle tract. These complications are rarely clinically significant.

ETANERCEPT.

Etanercept is a genetically engineered fusion protein consisting of two identical chains of the recombinant extracellular tumor necrosis factor (TNF) receptor monomer fused with the Fc domain of human IgG1. Etanercept binds both TNFa and lymphotoxin-a (formerly called TNFß) and inhibits their activity. A randomized, double-blind, placebo-controlled trial of etanercept (0.4?mg/kg subcutaneously, twice weekly) in children with active polyarticular JRA who had failed methotrexate treatment reported that 74% demonstrated significant clinical improvement after 3 mo of therapy. The children who responded to etanercept were then randomized in a double-blind fashion to either continue treatment with etanercept or begin placebo injections. A significant difference in the frequency of patients who experienced flares (28% versus 81%, $p = .003$) and the time to demonstrate flare (median of 28 versus >116 days, $p > .001$) provided evidence in favor of continued treatment with etanercept. The overall frequency and type of adverse events documented in this trial were similar for etanercept and placebo except for injection site reactions and frequency of upper respiratory tract infections, which were both significantly increased among the etanercept-treated subjects. Based on this study, the FDA approved etanercept for the treatment of children with moderate to severe active polyarticular course JRA who have had an inadequate response to one or more second line agents. Etanercept is perhaps helpful in the control of JRA-associated uveitis that is inadequately unresponsive to standard steroid therapy. The role of TNF blockade in the treatment of a variety of rheumatic diseases in both children and adults is still evolving and requires additional longitudinal experience to establish long-term effectiveness and safety. Etanercept is only one of several biologic agents developed to inhibit TNF, but currently it is the only one approved for use in children. TNF is known to have a variety of beneficial functions, and the safety of long-term suppression of TNF function is unknown. TNF blockade is associated with an increased frequency of systemic infections and should not be started in subjects with history of chronic or frequent recurrent infections. Tuberculosis should always be excluded before beginning treatment. TNF blockade has also been shown to be efficacious for treatment of Crohn disease, psoriasis, and psoriatic arthritis, and is being evaluated for treatment of Wegener granulomatosus, spondyloarthropathy, juvenile dermatomyositis, and idiopathic inflammatory myositis in adults.

OTHER DRUGS.

Various other medications are used in the treatment of the rheumatic diseases in selected children. **Hydroxychloroquine** sulfate is an antimalarial drug that has an important role in the treatment of SLE and possibly dermatomyositis. Blinded withdrawal of hydroxychloroquine in patients with SLE resulted in a significantly higher frequency of disease worsening compared with placebo. It is especially helpful in the treatment of the cutaneous aspects of SLE and dermatomyositis. It is used infrequently to treat JRA because a prospective trial in patients with JRA failed to demonstrate increased efficacy of hydroxychloroquine compared with placebo. Hydroxychloroquine is given in a dose of 3–6?mg/kg/24?hr; a 3–6 mo trial is necessary to assess therapeutic response. Potential adverse effects include bone marrow suppression, CNS stimulation, gastric irritation, myasthenia-like weakness, and skin rash. The most significant potential side effect is retinal toxicity, which occurs very rarely but may result in blindness or loss of central vision. Complete ophthalmologic examinations including peripheral vision and color fields at baseline every 4–6 mo are mandatory during hydroxychloroquine treatment. The frequency of retinal toxicity is rare (approximately 1/5,000 patients).

Sulfasalazine has been used for many years in the treatment of inflammatory bowel disease. In a randomized, double-blinded, placebo-controlled study of children with JRA, sulfasalazine 50?mg/kg/24?hr (maximum 2,000?mg/24?hr) demonstrated significantly greater improvements in joint inflammation, global assessments, and laboratory parameters when compared with placebo. However, more than 30% of the sulfasalazine-treated patients withdrew from the study because of adverse effects, primarily gastrointestinal irritation and skin rashes. Although none of the adverse effects in this trial was serious, sulfasalazine has been associated with severe systemic hypersensitivity reactions, especially development of the Stevens-Johnson syndrome. These reactions are much more common in patients with active systemic JRA treated with sulfasalazine. The proper role for sulfasalazine

in treatment of children with JRA is still evolving. In most centers it is used in polyarticular and pauciarticular JRA and spondyloarthropathy.

Intravenous immunoglobulin (IVIG) is efficacious in various clinical conditions. IVIG has been proven to significantly improve the short- and long-term natural history of Kawasaki disease. Open studies have supported benefit for SLE-associated thrombocytopenia, systemic and polyarticular JRA, and dermatomyositis. A placebo-controlled crossover study demonstrated significant short-term benefit of IVIG in adults with active myositis, although the effect was short-lived after cessation of the therapy. Doses of IVIG generally used in these investigations have been large, 1–2?g/kg/dose, and must be given on a regular basis, usually monthly, to maintain benefit. In addition to being expensive and periodically in short supply, IVIG has been associated with severe systemic allergic reactions and postinfusion aseptic meningitis. IVIG seems to hold promise as a treatment for dermatomyositis, although no controlled trials have involved children.

Cyclophosphamide has been evaluated in controlled trials in both SLE and Wegener granulomatosis. Pulse intravenous cyclophosphamide (500–1,000?mg/m^2) given monthly for 6 mo, then every 3 mo for 12 mo, has been shown to reduce the frequency of renal failure in patients with SLE with diffuse proliferative glomerulonephritis. Open trials also suggest efficacy in severe CNS lupus. Oral cyclophosphamide (2?mg/kg/24?hr) is effective in the treatment of severe Wegener granulomatosis. Cyclophosphamide, an alkylating agent, requires metabolic conversion in the liver to its active metabolites, which alkylate the guanine in DNA, leading to the observed immunosuppression by the inhibition of the S2 phase of mitosis. Decreases in the numbers of T and B lymphocytes result in decreased humoral and cellular immune responses. Cyclophosphamide is a potent cytotoxic drug that is, however, associated with significant short- and long-term toxicities. Potential short-term adverse events include alopecia, nausea, vomiting, anorexia, oral and gastrointestinal tract ulcerations, cystitis, and bone marrow suppression. Long-term complications include an increased risk for sterility and cancer, especially leukemias, lymphomas, and bladder cancer. In adult women with SLE treated with intravenous cyclophosphamide, the overall frequency of permanent sterility has been reported to be 30–40%.

Cyclosporine has been introduced in the treatment of dermatomyositis and active systemic JRA based on uncontrolled clinical studies. Several drugs commonly used in the past are very seldom used currently, including salicylates, gold compounds, azathioprine, and d-penicillamine.

Future Treatments.

Rheumatologists have commonly combined several drugs in the treatment of rheumatic diseases to achieve better disease control, often to permit the use of lower dose of steroids. However, only in the last few years have prospective studies been performed to test the efficacy of various combination drug therapies. In adults with rheumatoid arthritis, a combination

of methotrexate, hydroxychloroquine, and sulfasalazine has been well tolerated. The combination of these three drugs was more efficacious than any of the drugs taken singly, or any combination of two of the three drugs. In an open study of children with severe systemic JRA, a combination of intravenous methylprednisolone, intravenous cyclophosphamide, and oral methotrexate demonstrated excellent short-term safety and clinical effect. It is anticipated that the development of standardized, sensitive outcome measures and large international consortiums of pediatric rheumatologists will allow various combination therapies to be critically evaluated in clinical trials in children with JRA and other rheumatic diseases.

In addition to inhibitors of TNF, a wide variety of other biologic agents are being studied in adults and many more are in development to modulate individual cell populations or molecular species involved in inflammatory processes. Monoclonal antibodies are being tested that can suppress specific T-cell subpopulations, bind particular cytokines or cytokine receptors, or inhibit anti–double-stranded DNA autoantibodies. These monoclonal antibodies are being widely tested in adults with rheumatic diseases, primarily rheumatoid arthritis and SLE. The potential for these therapies in children with rheumatic diseases is great but largely untested at this time.

Chapter 145 - Juvenile Rheumatoid Arthritis

Michael L. Miller
James T. Cassidy

Juvenile rheumatoid arthritis (JRA) is one of the most common rheumatic diseases of children and a major cause of chronic disability. It is characterized by an idiopathic synovitis of the peripheral joints, associated with soft tissue swelling and effusion. In the classification criteria of the American College of Rheumatology, JRA is regarded not as a single disease but as a category of diseases with three principal types of onset: (1) oligoarthritis, or pauciarticular disease, (2) polyarthritis, and (3) systemic-onset disease (Box 145–1). Nine distinct course subtypes have also been identified. The European League Against Rheumatism (EULAR) has also published classification criteria for a similar constellation of diseases, identified as juvenile chronic arthritis. New international criteria for the classification of seven specific types of onset of peripheral arthritis in children are being developed.

Etiology.

The etiology of the diseases classified under JRA is unknown. At least two events are considered necessary: immunogenetic susceptibility and an external, presumably environmental, trigger. Specific HLA subtypes have been identified as rendering children at risk, which may confer varying degrees of susceptibility, or indeed protection, depending on the age of the child. Possible external triggers for JRA include certain viruses (e.g., parvovirus B19, rubella, Epstein-Barr virus), host hyperreactivity to specific self-antigens (type II collagen), and enhanced T-cell reactivity to bacterial or mycobacterial heat shock proteins.

Epidemiology.

Although difficult to determine with precision, the incidence of JRA is approximately 13.9/100,000 children/yr among children 15 yr or younger, with an overall prevalence of approximately 113/100,000 children. A report from Australia, however, provided a much higher estimate of prevalence based on examination of school children by a pediatric rheumatologist. This study suggested a need for increased identification and referral of children with arthritis to pediatric rheumatology treatment centers. Different racial and ethnic groups appear to have varying frequencies of the subtypes of JRA. One study reported that black American children with JRA were older at presentation and less likely to have elevated antinuclear antibody (ANA)

titers or uveitis.

Pathogenesis.

The synovitis of JRA is characterized by villous hypertrophy and hyperplasia with hyperemia and edema of the subsynovial tissues. Vascular endothelial hyperplasia is prominent and characterized by infiltration of mononuclear and plasma cells (Fig. 145–1). Pannus formation occurs in advanced or uncontrolled disease and results in progressive erosion of articular cartilage and contiguous bone (Fig. 145–2).

Although the etiology is unknown, studies suggest exaggerated immune reactivity of several types of cells in predisposed children, suspected but not proved to be in response to exposure to certain viruses. Thus, the onset of JRA may be triggered by a preceding infection. Although trauma may be cited by the

Box 145-1. Criteria for the Classification of Juvenile Rheumatoid Arthritis

- Age at onset <16 yr
- Arthritis (swelling or effusion, or presence of two or more of the following signs: limitation of range of motion, tenderness or pain on motion, and increased heat) in one or more joints
- Duration of disease 6 wk or longer
- Onset type defined by type of disease in first 6 mo:
  - Polyarthritis: 5 or more inflamed joints
  - Oligoarthritis: <5 inflamed joints
  - Systemic: arthritis with characteristic fever
- Exclusion of other forms of juvenile arthritis

Modified from Cassidy JT, Levison JE, Bass JC, et al: A study of classification criteria for a diagnosis of juvenile rheumatoid arthritis. Arthritis Rheum 1986;29;174.

Modified from Cassidy JT, Levison JE, Bass JC, et al: A study of classification criteria for a diagnosis of juvenile rheumatoid arthritis. Arthritis Rheum 1986;29;174.

parents as a trigger, it is more likely the result than the cause of arthritis. Studies of T-cell receptor expression confirm recruitment of T cells specific for antigens, at present uncharacterized, which are present in joint synovium. Specific populations of

Figure 145-2 MRI scan with gadolinium of a 10-yr-old child with juvenile rheumatoid arthritis (same patient as in Fig. 145–1). The dense white signal in the synovium near the distal femur, proximal tibia, and patella reflects inflammation. MRI is useful to exclude ligamentous injury, chondromalacia of the patella, or tumor.

T cells appear to change over time, sometimes with clonal expansion of cells that may be protective (e.g., those reactive toward certain heat shock proteins) and associated with improved responsiveness to medical treatment. However, resistance to treatment may result in part from the migration into synovium of T cells whose surfaces bear molecules permitting chronic activation.

The recruitment of these T cells is made possible by certain HLA types that are found with increased frequency in affected children. HLA-DR4 (particularly the DRB1*0401 allele) is associated with polyarticular disease; pauciarticular JRA has been associated with HLA alleles at the DR8 (particularly DRB1*0801) and DR5 (particularly DRB1*1104) loci.

T-cell activation results in a cascade of events leading to tissue damage in joints and other affected tissues, including B-cell activation, complement consumption, and, in particular, release of interleukin-6 (IL-6), IL-13, tumor necrosis factor-a (TNFa), and other pro-inflammatory cytokines, possibly under the control of specific genetic alleles. Inheritance of certain alleles may predispose to production of greater amounts of these cytokines, resulting in more severe disease.

Clinical Manifestations.

Initial symptoms often include morning stiffness and gelling, easy fatigability particularly after school in the early afternoon, joint pain later in the day, and joint swelling. The involved joint is often warm, lacks full range of motion, and is occasionally painful on motion but usually not erythematous.

Oligoarthritis (pauciarticular disease) predominantly affects the joints of the lower extremities, such as the knees and ankles (Fig. 145–3). Involvement of upper extremity large joints, although seen, is not characteristic of this type of onset. Involvement of the hip is almost never a presenting sign of JRA. However, hip disease may occur later, particularly in polyarticular JRA, and is often the first sign of

a deteriorating functional course (Fig. 145–4).

Polyarthritis (polyarticular disease) is generally characterized by involvement of both large and small joints (Figs. 145–5 and 145–6). As many as 20–40 separate joints are often affected, although inflammation of only five or more joints is

Figure 145-3 Pauciarticular juvenile rheumatoid arthritis with involvement of the left knee and hands. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases; Copyright 1991, 1995, 1997. Used by permission of the American College of Rheumatology.)

required as a criterion for classification of this type of onset or course. Polyarticular disease often resembles the usual presentation of adult rheumatoid arthritis. Rheumatoid nodules found on extensor surfaces of elbows and over the Achilles tendon are associated with a more severe course. Micrognathia reflects chronic temporomandibular joint involvement. Cervical spine involvement of the apophyseal joints (Fig. 145–7) occurs frequently, with risk of atlantoaxial subluxation.

Systemic-onset disease is manifest by arthritis and prominent visceral involvement including hepatosplenomegaly, lymphadenopathy, and serositis, such as a pericardial effusion. It is

Figure 145-4 Severe hip disease in a 13-yr-old boy with active, systemic-onset juvenile rheumatoid arthritis. X-ray shows destruction of the femoral head and acetabula, joint space narrowing, and subluxation of left hip. The patient had received corticosteroids systemically for 9 yr.

characterized by a quotidian fever with daily temperature spikes to at least 39℃, sometimes followed by mildly hypothermic temperatures, for a minimum of 2 wk. Each febrile episode is often accompanied by a characteristic faint, erythematous, macular rash; these evanescent **salmon-colored** lesions may be linear or circular, from 2 to 5?mm in size, distributed most commonly over the trunk and proximal extremities (Fig. 145–8). **Koebner phenomenon**, which is cutaneous hypersensitivity to superficial trauma, is elicited by lightly running the edge of the examiner's fingernail along uninvolved skin, is suggestive, but not diagnostic, of systemic-onset disease.

Diagnosis.

The diagnosis of JRA is greatly aided by the American College of Rheumatology classification criteria and its subclassification of courses of disease and by the meticulous exclusion of other articular diseases. There is no one pathognomonic finding for these diseases in children. However, the classic intermittent fever in association with the typical rash and objective arthritis is highly suggestive of systemic-onset JRA. The diagnosis is based on a history compatible with inflammatory joint disease and a physical examination that confirms the presence of arthritis, as defined by the classification criteria (see Box 145–1). Laboratory abnormalities characteristic of inflammation include an elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), leukocytosis, thrombocytosis, and the anemia of chronic disease support the diagnosis.

DIFFERENTIAL DIAGNOSIS.

Arthritis can be the presenting manifestation for any of the rheumatic diseases of childhood, including systemic lupus erythematosus (SLE) (see Chapter 148), juvenile dermatomyositis (see Chapter 149), sarcoidosis (see Chapter 155), and the vasculitis syndromes (see Chapter 157). The diagnosis of these diseases will depend on specifically associated manifestations. In scleroderma, the swelling along the digits early in the disease is not confined to the joints, and subsequent loss of motion occurs without articular swelling. Rheumatic fever is characterized by exquisite joint tenderness, high spiking fevers, and polyarthritis that is usually migratory but may also be additive. Autoimmune hepatitis can be associated with arthritis. Lyme disease (see Chapter 204) should be considered in children living in or visiting endemic areas who present with oligoarthritis. Although a history of tick exposure, preceding flulike illness, and subsequent rash should be sought, these are not always present. Joint pain and swelling of a single joint suggests trauma or infection; correlation with history, laboratory, and radiologic findings helps exclude these possibilities.

Figure 145-5 Hands and wrists of a girl with rheumatoid factor-negative polyarticular juvenile rheumatoid arthritis. Notice the symmetric involvement of the metacarpophalangeal joints, proximal interphalangeal joints, and distal interphalangeal joints. Both wrists are affected.

Monoarticular arthritis unresponsive to anti-inflammatory treatment may be the result of chronic mycobacterial or other infection; the diagnosis is established by synovial biopsy.

Physical findings may suggest other diagnoses. Arthritis and fluid in a single joint suggests bacterial infection, although joint fluid can be significant with JRA, including in the knee joint resulting in a ballotable patella. Chondromalacia of the patella or related femoropatellar syndromes can cause knee pain. Tenderness over insertion of ligaments and tendons raises the possibility of a spondyloarthropathy. Pauciarticular arthritis occurring in an unusual distribution (e.g., small joints of the hand and ankle) can be seen in psoriatic arthritis. However, until psoriasis develops, which may occur years after the arthritis

Figure 145-6 Progression of joint destruction in a girl with rheumatoid factor-positive juvenile rheumatoid arthritis despite doses of corticosteroids sufficient to suppress symptoms in the interval between *A* and *B*. *A*, Roentgenogram of the hand at onset. *B*, Roentgenogram 4 yr later, showing a loss of articular cartilage and destruction changes in the distal and proximal interphalangeal and metacarpophalangeal joints and destruction and fusion of wrist bones.

presents, the diagnosis can only be suspected. Isolated hip pain with limited motion raises the possibility of suppurative arthritis, osteomyelitis, Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, and chondrolysis of the hip.

Some children will have persistent arthralgia despite repeated normal physical examination. Although these children do not fulfill the diagnostic criteria for JRA initially, the diagnosis of JRA may sometimes be established as long as 2 yr after initial presentation. Until persisting joint swelling develops, other diagnoses need to be considered. Episodes of joint pain and swelling, usually lasting less than 1 wk with complete resolution between episodes, can be seen in juvenile episodic arthritis, often attributed to hypermobility syndrome. Inflammatory bowel disease may present with pauciarticular arthritis, usually affecting joints in the lower extremities. The presence of diarrhea in a child with arthritis can also follow an enteric infection (see Chapter 147). A fear of returning to school suggests school phobia.

Less commonly, other diseases can produce joint symptoms and abnormal joint examination. Children with leukemia may have joint pain resulting from metaphyseal expansion of malignant bone marrow, sometimes months before demonstrating peripheral blood lymphoblasts. Examination of such a child usually reveals a deeper pain to palpation of the bone; bone marrow aspiration yields the diagnosis. Some diseases, such as cystic fibrosis, diabetes mellitus, and glycogen storage diseases, have associated arthropathies. Swelling that extends beyond the joint can be seen in lymphedema, which may rarely coexist with JRA, and in Henoch-Schönlein purpura. A peripheral arthritis indistinguishable from types of JRA occurs in the presence of humoral immunodeficiency, such as common variable immunodeficiency and X-linked agammaglobulinemia. Some skeletal dysplasias associated with a degenerative arthropathy can be diagnosed by characteristic radiologic abnormalities.

Laboratory Findings.

Hematologic abnormalities often reflect the degree of systemic or articular inflammation, with elevated white blood cell and platelet counts and decreased hemoglobin concentration and mean corpuscular volume. The ESR and

Figure 145-7 Radiograph of the cervical spine of a patient with active juvenile rheumatoid arthritis, showing fusion of the neural arch between joints C2-3, narrowing and erosion of the remaining neural arch joints, obliteration of the apophyseal space, and loss of the normal lordosis.

Figure 145-8 The rash of systemic-onset juvenile rheumatoid arthritis. The rash is salmon colored, macular, and nonpruritic. Individual lesions are transient and occur in crops over the trunk and extremities. (Reprinted from the Clinical Slide Collection on the Rheumatic Diseases; Copyright 1991, 1995, 1997. Used by permission of the American College of Rheumatology.)

CRP usually mirror these findings, along with elevated serum immunoglobulins. However, it is not unusual for the ESR to be normal in some children with JRA, probably when most activated lymphocytes responsible for disease have shifted from the bloodstream and entered the synovium.

Elevated ANA titers are present in at least 40–85% of all children with pauciarticular or polyarticular JRA but are unusual in children with systemic-onset disease. Detectable ANA, usually with homogeneous or speckled pattern, is associated with increased risk for the development of chronic uveitis but the precise specificities for various ANA patterns have not been determined. A positive rheumatoid factor (RF) may be associated with onset of the disease in an older child with polyarticular involvement (approximately 8%) and the development of rheumatoid nodules, and with a poor overall prognosis and eventual functional disability. Both ANA and RF can occur in association with transient events during childhood, such as viral infections, particularly Epstein-Barr virus; seropositivity must be defined at a specific titer within a laboratory in relation to accepted positive and negative controls and based on consecutive positive tests over a defined period.

Bone mineral metabolism is often abnormal in children with JRA with a history of active synovitis, relatively independent of onset type or course subtype, and predominantly affects appendicular cortical bone, with less effect upon the normal age-related development of trabecular bone. Increased levels of cytokines such as IL-6 may decrease bone formation (reflected by decreased serum levels of osteocalcin and bone-specific alkaline phosphatase) to a greater extent than bone resorption (which may also be decreased, as reflected by decreased levels of tartrate-resistant acid phosphatase). Corresponding abnormalities of skeletal growth become most prominent during the pubertal growth spurt and in postpubertal children (Tanner stages IV–V).

Early radiographic changes include soft tissue swelling, osteoporosis, and periostitis about the affected joints (Fig. 145–9). Regional epiphyseal closure may be accelerated and the local bone growth increased or decreased. Continued disease may lead to subchondral erosions and narrowing of cartilage space, with varying degrees of bony destruction and fusion. Characteristic late radiographic changes of JRA are seen in the hands and cervical spine, most frequently in the neural arch joints at C2-3 (see Fig. 145–7). MRI studies may be helpful to evaluate both joint and soft tissues (see Fig. 145–2).

Treatment.

The long-term treatment of children with JRA is initiated and subsequently modified according to disease subtype, severity of the disease, specific manifestations of the illness, and response to therapy. The objectives of treatment are to establish the child in a pattern of adaptation that is as normal as possible

Figure 145-9 Early (6-mo duration) radiographic changes of juvenile rheumatoid arthritis, soft tissue swelling, and periosteal new bone formation appear adjacent to the 2nd and 4th proximal interphalangeal joints.

and to accomplish this goal with minimal risk of adverse effects (see Chapter 144).

Most children with oligoarticular JRA respond to nonsteroidal anti-inflammatory drugs (NSAIDs) alone. However, most polyarticular patients, and some oligoarticular patients with aggressive disease, require additional medications. A pyramid therapeutic approach should be considered; combination therapy should begin with the least toxic medications, usually NSAIDs, and proceeding through sulfasalazine, methotrexate, and possibly etanercept or immunosuppressive or experimental drugs (Fig. 145–10). Medications that place the child's present and future health most at risk, such as azathioprine and cyclophosphamide, are reserved for the very few children who do not respond to less aggressive therapy. Newer modes of treatment, such as etanercept, may prove to be more specific for synovial inflammatory disease and potentially less toxic than other current medications.

Glucocorticoids are used for management of overwhelming inflammatory or systemic illness, for **bridge therapy** in lower doses for the child who has not yet responded, in addition to another drug such as methotrexate, and for ocular and intra-articular use. Corticosteroids are very powerful anti-inflammatory drugs, perhaps the most efficacious in current use for systemic disease, but they may be associated with tachyphylaxis and impose upon the child the risk of severe toxicities, including Cushing syndrome, growth retardation, and osteopenia.

Methotrexate is considered the safest, most efficacious, and least toxic of the currently available second-line agents. It may be given either orally or subcutaneously once weekly. Intramuscular gold therapy has been generally supplanted by methotrexate.

Other aspects of management include routine slit-lamp ophthalmologic examination of all patients with JRA to monitor for development of asymptomatic uveitis, dietary evaluation and counseling to ensure appropriate calcium intake, and physical and occupational therapy. Social workers can help families recognize stresses imposed by illness and identify appropriate community resources.

Prognosis.

Although the course of JRA in an individual child is unpredictable, some general statements can be made concerning onset type and outcome (Table 145–1). Studies from the United States indicate that, despite current management, approximately 45% of JRA patients have active disease persisting into early adulthood, often with severe limitations of physical function.

TABLE 145-1 -- Prognosis of Juvenile Rheumatoid Arthritis by Type of Onset

Onset Type	Course Subtype	Subsequent Clinical Manifestations	Outcome
Polyarthritis	RF-seropositive	Female	Poor
		Older age	
		Hand/wrist	
		Erosions	
		Nodules	
		Unremitting	
	ANA-seropositive	Female	Good
		Young age	
	Seronegative	—	Variable
Oligoarthritis	ANA-seropositive	Female	Excellent (except eyes)
		Young age	
		Chronic anterior uveitis (iridocyclitis)	
	RF-seropositive	Polyarthritis	Poor
		Erosions	
		Unremitting	
	HLA-B27–positive	Male	Good
		Older age	
	Seronegative	—	Good
Systemic disease	Oligoarthritis	—	Good
	Polyarthritis	Erosions	Poor

Figure 145-10 The “therapeutic pyramid” of juvenile rheumatoid arthritis. (Adapted from Cassidy JT, Petty RE: Juvenile rheumatoid arthritis. In *Textbook of Pediatric Rheumatology*, 3rd ed. Philadelphia, WB Saunders, 1995.)

Children with oligoarthritis, particularly girls with early onset of arthritis at younger than 6 yr of age, are at risk to develop chronic uveitis. There is usually no association between the course of the arthritis and the chronic uveitis. Anterior uveitis (Fig. 145–11), or iridocyclitis, in children with pauciarticular disease can result in posterior synechiae; untreated or refractory uveitis can result in blindness, which has decreased with more frequent monitoring by slit-lamp examination to exclude asymptomatic uveitis. Many of these children do well, however, with early remission.

The child with polyarticular disease often has a more prolonged course. Functional risk has been associated with older age of onset, the presence of rheumatoid factor seropositivity or

Figure 145-11 Chronic anterior uveitis, or iridocyclitis, of juvenile rheumatoid arthritis. Extensive posterior synechiae have resulted in a small, irregular pupil. There is a well-developed cataract and early band keratopathy at the medial and lateral margins of the cornea.

rheumatoid nodules, and the early development of specific articular disease, such as that affecting the cervical spine or hips.

The child with systemic-onset disease is often the most difficult to manage in terms of both articular and systemic manifestations. However, systemic manifestations are usually present only during the first few years after onset. The prognosis after that time is dependent on the number of joints involved and severity of the arthritis.

Anemia, common in active disease or disease of prolonged duration, is usually unresponsive to oral iron administration. Anemia may be exacerbated by gastrointestinal bleeding associated with the use of NSAIDs. Specific complications may occur in subsets of the disease, such as the development of SLE during the course of disease in children with polyarticular JRA, particularly when they develop ANAs with a high titer. Anemia associated with decreases in other blood cell lines raises the possibility of malignancy. Rarely, anemia is a result of hemolytic anemia. Anemia associated with thrombocytopenia or leukopenia with fever, lymphadenopathy, and hepatosplenomegaly suggests **macrophage activation syndrome**, a rare complication of systemic JRA. This diagnosis is confirmed by liver or bone marrow biopsy. Treatment with cyclosporine has been effective in many patients. A rare digital endarteritis threatening autoamputation may respond to parenterally administered prostaglandin E_1 . The development of manifestations of other rheumatic diseases suggests that the diagnosis has changed to an overlapping syndrome or another specific disease, such as SLE or dermatomyositis.

Orthopedic complications include leg length discrepancy, which can be treated with a shoe lift on the shorter side to prevent a secondary scoliosis; popliteal cysts, which require no treatment if small; and flexion contractures, particularly of the knees, hips, and wrists. Contractures require medical control of arthritis, appropriate splinting, and a physical therapy program to allow stretching of affected tendons.

Psychosocial adaptation may be affected by JRA. Studies from Scandinavia and the United States indicate that, compared with control subjects, many of these children have problems with lifetime adjustments and obtaining employment. Disability not directly associated with arthritis may continue into young adulthood in as many as 20% of patients, together with continuing chronic pain syndromes in a similar frequency. Psychologic complications, including problems with school attendance and socialization, may respond to counseling by mental health professionals.

Chapter 146 - Ankylosing Spondylitis and Other Spondyloarthropathies

Michael L. Miller
Ross E. Petty

The diseases collectively referred to as **spondyloarthropathies** include ankylosing spondylitis, the psoriatic arthritides, arthritis accompanying inflammatory bowel diseases, and chronic reactive arthritis following enteric or genitourinary (GU) tract infections. In the new classification of the International League of

Associations for Rheumatology (ILAR), the term **enthesitis-related arthritis** is used to denote what has traditionally been called juvenile ankylosing spondylitis; psoriatic arthritis is considered distinct.

Epidemiology.

Estimates of the prevalence of juvenile ankylosing spondylitis (JAS) range from 11–86/100,000 children, and of psoriatic arthritis from 10–15/100,000 children. JAS occurs most frequently in older boys, adolescents, and young adults. These disorders are frequently familial; the histocompatibility antigen HLA-B27 is strongly associated with JAS (>90%) and is found in increased frequency in persons having spondyloarthropathies with inflammation of the axial skeleton.

Psoriatic arthritis is particularly common in young girls. The arthropathies of inflammatory bowel diseases, reactive arthritis, and Reiter syndrome (a symptom complex consisting of arthritis, urethritis, and conjunctivitis usually associated with HLA-B27) are much less common in childhood; they can affect children of any age and are somewhat more common in boys.

Pathogenesis.

The histologic appearance of the synovium in spondyloarthropathies is indistinguishable from that of other idiopathic chronic arthritides. Tenosynovitis may

be present, and periostitis may occur. **Enthesitis** (inflammation at the sites of attachments of ligaments, tendons, fascias, and capsules to bone) is characterized by chronic inflammation and, in advanced disease, which is usually found in adults, by calcification of ligaments and fusion of joints.

Chronic reactive arthritis may follow enteric infection with nontyphoidal *Salmonella*, *Shigella*, *Yersinia enterocolitica*, *Campylobacter jejuni*, *Cryptosporidium parvum*, or *Giardia intestinalis*, or GU tract infection with *Chlamydia trachomatis*. The cause of the other spondyloarthropathies is unknown. It is postulated that similarity between self-antigens and bacterial antigens (**molecular mimicry**) permits the development of an autoimmune process in genetically predisposed individuals.

Clinical Manifestations.

The spondyloarthropathies are characterized by inflammation of joints of the axial skeleton as well as the limbs, by the presence of enthesitis, and by the absence of rheumatoid factor.

JUVENILE ANKYLOSING SPONDYLITIS.

Early JAS is most frequently characterized by oligoarthritis and enthesitis. Joints of the legs are more frequently affected than those of the arms. Abnormalities of the axial skeleton including the sacroiliac joints are usually absent until later in the disease course, although loss of spinal flexibility may eventually be noted (Fig. 146–1). When few joints are affected during the first 6 mo of disease, hip joint arthritis is particularly suggestive of early JAS. Enthesitis, presenting as localized tenderness at characteristic locations around the foot and knee, is particularly common and has led to the description of a syndrome of seronegativity (absence of rheumatoid factor), enthesitis, and arthritis (SEA syndrome), which is probably the most common initial presentation of JAS. The disease course may be characterized by long periods of apparent disease remission. Systemic symptoms such as low-grade fever and weight loss raise the possibility of occult inflammatory bowel disease.

PSORIATIC ARTHRITIS.

The most common pattern of psoriatic arthritis is oligoarthritis, which affects large and small joints in an asymmetric pattern. Patients with psoriatic arthritis occasionally have symmetric distal interphalangeal joint disease, or HLA-B27-associated sacroiliitis, although most patients are HLA-B27-negative and do not have arthritis of the sacroiliac joints or lumbosacral spine. The presence of nail pitting (Fig. 146–2), dactylitis, onycholysis, or a family history of psoriasis supports the diagnosis of psoriatic arthritis in a child with oligoarthritis or polyarthritis.

ARTHRITIS WITH INFLAMMATORY BOWEL DISEASE.

Two patterns of arthritis complicate Crohn disease and ulcerative colitis. A polyarthritis affecting large and small joints, which reflects the activity of the intestinal inflammation, is most common and is not truly a spondylarthritis because it does not affect joints of the spine and is not associated with HLA-B27. Less commonly, arthritis of the sacroiliac joints and other peripheral joints occurs in a pattern similar to that in ankylosing spondylitis, which, in most instances, is associated with HLA-B27. Its severity is independent of the activity of the gastrointestinal (GI) inflammation.

Figure 146-1 Loss of lumbodorsal spine mobility in a boy with ankylosing spondylitis: The lower spine remains straight when the patient bends forward.

REACTIVE ARTHRITIS.

Reactive arthritis, including the syndrome of arthritis, urethritis, and conjunctivitis, is usually preceded by GI or GU infection. The arthritis is usually oligoarticular and may be quite severe, with considerable swelling, pain, and even erythema. Joints of the lower limbs are most commonly affected. Unlike the more common clinical forms of self-limited postinfectious arthritis (see Chapter 147), the arthritis may become chronic, lasting from several weeks to years.

Figure 146-2 Nail pitting (*arrow*) and "sausage digit" (dactylitis) of the left index finger of a girl with juvenile psoriatic arthritis. (From Petty RE, Malleson P: Spondyloarthropathies of childhood. *Pediatr Clin North Am* 1986;33:1079.)

Enthesitis may be prominent, and sacroiliitis may eventuate in HLA-B27-positive patients.

Diagnosis.

The diagnosis of a spondyloarthropathy is suggested by the onset in an older child, particularly a boy, of oligoarthritis that predominantly affects the hips, knees, ankles, or feet (particularly the intertarsal joints), especially if accompanied by enthesitis. A diagnosis of ankylosing spondylitis is confirmed if there is radiographic evidence of sacroiliitis. Because radiographic changes seldom occur at onset, it may be difficult to differentiate spondylarthritis from oligoarticular juvenile rheumatoid arthritis (JRA) early during the disease course. The presence of synovitis in the upper extremities tends to be more common in patients with JRA than with spondyloarthropathies. In a child with chronic arthritis, the presence of erythema nodosum, pyoderma gangrenosum, significant fever, weight loss, or anorexia suggests inflammatory bowel disease. The acute onset of arthritis, a recent history of diarrhea, and symptoms of urethritis or conjunctivitis may suggest reactive arthritis. Psoriasis, nail changes (see Fig. 146–2), or a family history of psoriasis suggests the diagnosis of psoriatic arthritis in a child (often a young girl) with oligoarthritis or polyarthritis. Early differentiation among the spondyloarthropathies by laboratory or radiographic means is difficult. Sacroiliac joint change or enthesitis may be seen on technetium-99 bone scan, but results of this examination are often difficult to interpret in children and adolescents.

Back pain may occur in children with early ankylosing spondylitis but could also be caused by suppurative arthritis of the sacroiliac joint, osteomyelitis of the pelvis or spine, osteoid osteoma of the posterior elements of the spine, or malignancies such as osteogenic sarcoma, Ewing sarcoma, or leukemia. In addition, mechanical causes such as spondylolysis, spondylolisthesis, and Scheuermann disease should be considered. Back pain secondary to fibromyalgia usually affects the soft tissues of the upper back in a symmetric pattern, as well as other well-localized tender points.

Hip joint arthritis is characterized by pain over the inguinal ligament and loss of internal rotation of the hip joint. Legg-Calvé-Perthes disease, slipped capital femoral epiphysis, and chondrolysis may have presentations similar to spondyloarthropathy.

Laboratory Findings.

Laboratory evidence of systemic inflammation is often present at the onset of disease, with elevated erythrocyte sedimentation rate and mild increase in white blood cell count and platelet count. Rheumatoid factor is absent in all children with spondyloarthropathies. Antinuclear antibodies are absent except in children with psoriatic arthritis, in whom antinuclear autoantibodies occur in as many as 50%. HLA-B27 is present in more than 90% of children with JAS but is probably not increased significantly in those with other types of spondylarthritis unless sacroiliitis or acute anterior uveitis is present.

Radiographic changes include periarticular osteoporosis, loss of sharp cortical margins in areas of enthesitis (which may eventually show erosions or bony spurs), indistinct margins and erosions of the sacroiliac joints, with sclerosis on the iliac side of the joint (Fig. 146–3), and, rarely, squaring of the corners of the vertebral bodies. The characteristic **bamboo spine** caused by calcification of ligaments that is so characteristic of advanced ankylosing spondylitis in adults is very rare in childhood.

Treatment.

The aims of therapy are to control inflammation, minimize pain, and preserve function. These are accomplished by a combination of anti-inflammatory medications, physical therapy, and psychosocial support. Nonsteroidal anti-inflammatory drugs such as naproxen (15–20?mg/kg/24?hr) may be sufficient. It may be necessary to add sulfasalazine (up to 50?mg/kg/24?hr, no more than 3?g/24?hr in adolescents). Intra-articular triamcinolone hexacetonide is useful for controlling localized joint

Figure 146-3 Well-developed sacroiliitis in a boy with ankylosing spondylitis; both sacroiliac joints show extensive sclerosis, erosion of joint margins, and apparent widening of the joint space.

inflammation. Exercises to maintain range of motion in the back, thorax, and affected joints should be instituted early in the disease course. Custom-fitted insoles are particularly useful in management of painful entheses around the feet.

Complications.

Acute iridocyclitis, or anterior uveitis, occurs in as many as 25% of patients with JAS. Chronic iridocyclitis similar to that in JRA occurs in approximately 15% of children with psoriatic arthritis. Aortic valve insufficiency is a rare but important complication of ankylosing spondylitis. Atlantoaxial subluxation has also been reported.

Prognosis.

There is little reliable information about long-term outcome of the spondyloarthropathies in childhood. These are chronic diseases with highly variable clinical courses. JAS is often characterized by long periods of active disease followed by long periods of inactivity. Most studies have shown that, over many years, the disease progresses to involve joints of the spine and sacroiliac joints and may cause fusion and significant disability. Psoriatic arthritis tends to be a chronic unremitting disease. Reactive arthritis may be brief (several weeks or months) but may become chronic and progress to ankylosing spondylitis. In children with inflammatory bowel disease, the peripheral arthritis is usually controlled when the GI inflammation is controlled; if the arthritis is associated with HLA-B27, the course tends to be more chronic.

Chapter 147 - Postinfectious Arthritis and Related Conditions

Michael L. Miller
James T. Cassidy

Infections have been associated with arthritis during their course and as a postinfectious reaction observed several weeks or months afterward. Although certain infectious organisms have been suspected but not proved to trigger juvenile rheumatoid arthritis (JRA), other agents are often associated with a transient arthritis that does not satisfy the classification criteria for JRA. **Reactive arthritis** follows an infection outside the joint, particularly the gastrointestinal or genitourinary tract. The course of reactive arthritis is variable and may progress to chronic spondyloarthropathy (see Chapter 146). **Postinfectious arthritis** implies arthritis that follows infections that are usually viral in origin, with shorter duration than reactive arthritis.

Pathogenesis.

Reactive arthritis may follow enteric infection with non-typhoidal *Salmonella, Shigella, Yersinia enterocolitica, Campylobacter jejuni, Cryptosporidium parvum,* or *Giardia intestinalis,* or genitourinary tract infection with *Chlamydia trachomatis*. Reactive arthritis may represent an autoimmune response involving T lymphocytes that cross-react to antigens in joints (**molecular mimicry**). A study of synovial fluid from patients with reactive arthritis suggested that T cells may be more engaged in promoting inflammation than in eliminating bacteria through cytotoxic mechanisms. However, the origin of these abnormal cells may be from outside the joint. Another possible mechanism is lymphocytic reactivity to bacterial DNA found in synovium, perhaps as a by-product of otherwise successfully cleared infection. One study of joint fluid from patients with reactive arthritis, using polymerase chain reaction amplification, demonstrated bacterial DNA. However, a relationship to specific clinical characteristics was not found.

Several viruses (rubella, varicella-zoster, herpes simplex, and cytomegalovirus) have been isolated from the joint space. Antigens from other viruses (hepatitis B, adenovirus 7) have been identified in immune complexes from joint tissue. Postinfectious arthritis following viral infections appears to involve the deposition in

joints of immune complexes containing viral antigens.

Certain HLA types may predispose to development of reactive arthritis, possibly by triggering autoreactive T lymphocytes. Adolescents and adults with reactive arthritis following enteric infections have shown persistent gut inflammation even after resolution of gastrointestinal manifestations, particularly in HLA-B27-positive individuals. Uveitis complicating reactive arthritis to *Y. enteritis* has also been associated with HLA-B27. Some children, often HLA-B27 positive, with reactive arthritis eventually develop spondyloarthropathy, further suggesting that HLA type predisposes to reactive arthritis.

Clinical Manifestations.

Bacterial enteritis caused by *Shigella, Salmonella, Yersinia*, and *Campylobacter* can be followed within days to several weeks by the development of arthritis and sometimes **enthesitis,** or inflammation of the muscular or tendinous attachment to bone, in a syndrome similar to and overlapping spondyloarthropathy (see Chapter 146). Although the erythrocyte sedimentation rate (ESR) may be elevated, fever and leukocytosis are often absent. Urethritis and conjunctivitis develop occasionally. Postinfectious arthritis following less apparent illness, such as viral upper respiratory tract infections, may precede arthralgia and arthritis by 1–2 mo. Symptoms of arthralgia and joint swelling are transient, usually lasting less than 6 wk.

Certain viruses associated with arthritis (Box 147–1) may result in particular patterns of joint involvement. Rubella and hepatitis B virus typically affect the small joints, and mumps and varicella often involve large joints, especially the knees. The hepatitis B **arthritis-dermatitis syndrome** is characterized by rash and arthritis resembling serum sickness. **Rubella-associated arthropathy** follows natural rubella infection and, infrequently, rubella immunization. It typically occurs in young women, with increased incidence with advancing age, and is uncommon in preadolescent children and in males. Arthralgias of the knees and hands usually begin within 7 days of onset of the rash or 10–28 days after immunization. Parvovirus B19, responsible for erythema infectiosum (fifth disease), can cause arthralgia, symmetric joint swelling, and morning stiffness in adults, particularly women, and less frequently in children. Arthritis occurs occasionally during cytomegalovirus infection and may occur during varicella infections, and is rare after Epstein-Barr virus infection. Varicella may also be complicated by suppurative arthritis, usually due to group A *Streptococcus*.

Arthritis has been reported in children with severe truncal acne, usually in male adolescents. Patients often have fever and superficial infection of skin lesions. Recurrent episodes may be associated with myopathy and may last for several months. Infective endocarditis can be associated with arthralgia, arthritis, or signs suggestive of vasculitis, such as Osler nodes, Janeway lesions, and Roth spots. Arthritis also occurs in children with *Mycoplasma pneumoniae* infections.

Poststreptococcal arthritis may follow infection with either group A or group G *Streptococcus*. Because valvular lesions have been documented by echocardiography after the acute illness in some of these children, some clinicians consider this to be an incomplete form of acute rheumatic fever (see Chapter 168.1). Certain HLA-DRB1 types may predispose children to develop either poststreptococcal arthritis or classic rheumatic fever. Poststreptococcal arthritis is pauciarticular, may affect the small and large joints, and persists for months, compared with the

Adapted from Cassidy JT, Petty RE: Arthritis related to infection. In Textbook of Pediatric Rheumatology. Philadelphia, WB Saunders, 1995, p 503.

typical course of migratory polyarthritis of rheumatic fever. The symptoms are usually mild and tend to resolve completely.

Transient synovitis (toxic synovitis) typically affects the hip joints, often after an upper respiratory tract infection. Boys from 3–10 yr of age are most commonly affected and have complaints of pain in the hip, thigh, or knee. The ESR and white blood cell count are usually normal. Radiologic or ultrasound examination may reveal widening of the joint space of the hip. Aspiration of the hip may be necessary to exclude suppurative arthritis. The cause of this relatively common syndrome is not known, but it is presumed to be a viral or postinfectious arthritis.

Diagnosis.

The diagnosis of reactive postinfectious arthritis is usually established by exclusion only after the arthritis has resolved. Acute arthritis affecting a single joint suggests suppurative arthritis; osteomyelitis may cause joint pain but is associated more often with focal bone pain over the site of infection. Arthritis associated with gastrointestinal symptoms or elevated liver function test results may be caused by infectious or autoimmune hepatitis. Arthritis or spondylarthritis may occur in some children with inflammatory bowel disease, either Crohn disease or chronic ulcerative colitis (see Chapter 317). When two or more blood cell lines show a progressive decrease in a child with arthritis, parvovirus infection, macrophage activation syndrome, and leukemia should be considered. Persistent arthritis suggests the possibility of rheumatic disease, including JRA, spondyloarthropathy, and systemic lupus erythematosus.

Treatment.

No specific treatment is necessary for reactive arthritis, except for relief of pain and the functional limitations of arthritis with nonsteroidal anti-inflammatory agents. If swelling or arthralgia recurs, further evaluation may be necessary to preclude active infection or evolving rheumatic disease, such as spondyloarthropathy, JRA, or systemic lupus erythematosus.

Complications and Prognosis.

Postinfectious arthritis following viral infections usually resolves without complications unless it is part of a severe viral infection affecting other organs, as with encephalomyelitis. Reactive arthritis, especially after bacterial enteric infection or genitourinary tract infection with *C. trachomatis*, has the potential for evolving to a chronic arthritis and spondyloarthropathy (see Chapter 146). Children with reactive arthritis following enteric infections occasionally develop inflammatory bowel disease months to years after onset. Both uveitis and carditis have been reported in some children diagnosed with reactive arthritis.

Chapter 148 - Systemic Lupus Erythematosus

Marisa S. Klein-Gitelman
Michael L. Miller

Systemic lupus erythematosus (SLE, or lupus), a rheumatic disease of unknown cause, is characterized by autoantibodies directed against self-antigens and resulting inflammatory damage to target organs including the kidneys, blood-forming cells, and the central nervous system (CNS). The natural history of SLE is unpredictable; patients may present with a history of many years of symptoms or with acute, life-threatening disease. Untreated SLE may be followed by spontaneous remission, years of smoldering disease, or rapid death. Because of its possible manifestations, SLE must be considered in the differential diagnosis of many problems, ranging from fevers of unknown origin to arthralgia, anemia, and nephritis. The initial presentation may be atypical such as parotitis, abdominal pain, transverse myelitis, or dizziness. Lupus should be considered in patients with multiorgan symptoms, usually with an abnormal complete blood count or urinalysis. Early diagnosis and treatment tailored to the particular problems of an individual patient can greatly improve the prognosis for what used to be a fatal disease.

Etiology.

The cause and disease mechanisms of SLE remain unknown. Many factors, including genetics, hormones, and the environment, contribute to the immune dysregulation in lupus. The hallmark is autoantibody production against many self-antigens, particularly DNA, as well as other nuclear antigens, ribosomes, platelets, coagulation factors, immunoglobulin, erythrocytes, and leukocytes. Elevated levels of autoantibodies, particularly anti–double-stranded DNA antibodies, are associated with circulating and tissue-bound immune complexes that lead to complement fixation and recruitment of inflammatory cells, and then to tissue injury.

Polyclonal activation of B lymphocytes results in elevated immunoglobulin levels, which may be one cause of elevated autoantibody levels. The mechanism for polyclonal activation is not yet understood. Possible causes include nonspecific response to an antigenic stimulus such as a viral agent or loss of tolerance to self-antigens by loss of suppressor T-lymphocyte function. Investigations have focused on the normal phenomenon of **apoptosis**, or programmed cell death, which is regulated by several proteins including *fas* and *bcl*-2. Dysregulation of apoptosis in SLE may lead to the presence of self-reactive lymphocytes that normally undergo

apoptosis before birth.

Other mechanisms may have a role in amplifying the manifestations of SLE. Defects in macrophage phagocytosis and handling of immune complexes have been described. The effects of sex hormones may be responsible for the predominance of females with SLE; one study found higher follicle-stimulating hormone and luteinizing hormone levels and lower free androgen levels in postpubertal boys and girls with SLE. SLE has been

associated with complement abnormalities including C1q, C2, and C4 deficiency, a high incidence of C4 null genes, and abnormal complement receptors. Exposure to the ultraviolet rays in sunlight can exacerbate SLE manifestations, perhaps through damage to nuclear material, resulting in release of DNA, which complexes with circulating anti-DNA antibodies.

Genetic associations in SLE are suggested by the frequent findings of antinuclear antibodies (ANAs), hypergammaglobulinemia, and SLE or other autoimmune diseases in family members of patients with SLE. Some HLA types (e.g., HLA-B8, HLA-DR2, and HLA-DR3) may occur with increased frequency among patients with SLE, depending on the racial and ethnic backgrounds of patients studied. **Drug-induced lupus** is a lupus-like disease that occurs after exposure to certain drugs, notably anticonvulsants, sulfonamides, and antiarrhythmic agents. Their similar structure to histone proteins may be one cause, because antihistone antibodies are found in many patients with drug-induced lupus.

Epidemiology.

The incidence of SLE is not known but varies by location and ethnicity. Prevalence rates of 4–250/100,000 have been reported, with decreased prevalence in white compared with Native American, Asian, Latin, and black American patients. Although onset before age 8 yr is unusual, SLE has been diagnosed during the 1st year of life. Female predominance varies from less than 4:1 before puberty to 8:1 afterward.

Pathogenesis.

Fibrinoid deposits are found in blood vessel walls of affected organs, whose parenchyma may contain hematoxylin bodies, most likely representing degenerated cell nuclei. Rheumatoid nodules and granulomas are also sometimes found in affected tissues.

Clinical Manifestations.

Patients can present with various manifestations (Table 148–1). Children most frequently present with fever, fatigue, arthralgia or arthritis, and rash. Symptoms may be intermittent or persistent. A detailed history and physical and laboratory examination can facilitate early diagnosis and treatment.

Cutaneous manifestations are frequently present. The characteristic **malar or butterfly rash** includes the nasal bridge and varies from an erythematous blush to thickened epidermis to scaly patches (Fig. 148–1). Rashes may be photosensitive and extend to all sun-exposed areas. Mucous membrane changes from vasculitic erythema to ulcers occur, particularly on palatal and nasal mucosa (Fig. 148–2). Discoid lesions are unusual in childhood. However, they occur more frequently as a manifestation of SLE than as discoid lupus erythematosis (DLE) alone; 2–3% of all DLE occurs in childhood. Other cutaneous manifestations include vasculitic-appearing erythematous macular eruptions (particularly on fingers, palms, and soles), purpura,

TABLE 148-1 -- **Presenting Manifestations of Systemic Lupus Erythematosus**

Target Organ	Manifestations
Constitutional	Fatigue, anorexia, weight loss, prolonged fever, lymphadenopathy
Musculoskeletal	Arthralgias, arthritis
Skin	Malar rash, discoid lesions, livedo reticularis
Renal	Glomerulonephritis, nephrotic syndrome, hypertension, renal failure
Cardiovascular	Pericarditis (cardiac tamponade)
Neurologic	Seizures, psychosis, stroke, cerebral venous thrombosis, pseudotumor cerebri, aseptic meningitis, chorea, global cognitive deficits, mood disorders, transverse myelitis, peripheral neuritis
Pulmonary	Pleuritic pain, pulmonary hemorrhage

Hematologic	Coombs-positive hemolytic anemia, anemia of chronic disease, thrombocytopenia, leukopenia

Figure 148-1 The butterfly rash of systemic lupus erythematosus. The rash can vary from an erythematous blush (*A*) to thickened epidermis to scaly patches (*B*).

livedo reticularis (Fig. 148–3), and Raynaud phenomenon. Less common findings include subacute psoriasiform or annular skin lesions, bullous lesions, and alopecia.

Musculoskeletal findings include arthralgia, arthritis, tendinitis, and myositis. Deforming arthritis is unusual; hand arthritis can lead to ligament damage and severely lax joints. Osteonecrosis of bone is common and is presumed to be secondary to vasculopathy or corticosteroid treatment.

Serositis can affect pleural, pericardial, and peritoneal surfaces. Hepatosplenomegaly and lymphadenopathy are often found. Other gastrointestinal manifestations, most often resulting from vasculitis, include pain, diarrhea, infarction and melena, inflammatory bowel disease, and hepatitis. Cardiac involvement may affect all cardiac tissues and include valvular thickening and verrucous endocarditis (Libman-Sacks disease), cardiomegaly, myocarditis, conduction abnormalities, heart failure, and coronary artery vasculitis and thrombosis. Pulmonary manifestations include acute pulmonary hemorrhage, pulmonary infiltrates (sometimes with superimposed infection), and chronic fibrosis.

Neurologic manifestations can include the CNS and peripheral nervous system (see Table 148–1). It is likely that many patients with SLE experience memory loss or other cognitive dysfunction during their disease course. Neuropsychiatric manifestations can be severe, and patients may fulfill Diagnostic and

Figure 148-2 Erythematous lesion involving the hard palate in a patient with systemic lupus erythematosus. (From Moschella S, Hurley H [editors]: *Dermatology*, 3rd ed. Philadelphia, WB Saunders, 1992.)

Statistical Manual of Mental Disorders (DSM IV) criteria for psychosis. MRI and CT images may be normal although abnormal single-photon emission CT images occur frequently. The occurrence of arterial or venous thrombosis (Fig. 148–4), suggestive of antiphospholipid antibody syndrome, can occur in any organ and can be associated with recurrent fetal loss, livedo reticularis, thrombocytopenia, and Raynaud phenomenon. Thrombotic events can also be associated with the presence of lupus anticoagulant and acquired, activated protein C resistance.

Figure 148-4 A 12-yr-old girl with systemic lupus erythematosus and antiphospholipid antibodies with painful cutaneous vasculitis of the right foot. Arterial thrombosis documented by angiography resulted in cyanosis of the large toe. Symptoms resolved with treatment with heparin and corticosteroids.

Renal disease is manifest by hypertension, peripheral edema, retinal vascular changes, and clinical manifestations associated with electrolyte abnormalities, nephrosis, or acute renal failure (see Chapter 505).

Diagnosis.

The diagnosis is confirmed by the combination of clinical and laboratory manifestations revealing multisystem disease. Criteria for the diagnosis of SLE require the presence of 4 of 11 criteria serially or simultaneously (Table 148–2). In 1997, criteria were revised to exclude LE prep and replace it with anticardiolipin antibodies or a positive test for lupus anticoagulant; however, this change has not been validated. A positive ANA test result is not required for diagnosis; however, absence of ANA is rare. Patients suspected to have lupus, even if with less than 4 criteria, should receive appropriate medical treatment. Hypocomplementemia is not diagnostic; extremely low levels or absence of total hemolytic complement suggests the possibility of complement component deficiency. Renal biopsy is used to confirm diagnosis of lupus nephritis and to determine treatment.

Laboratory Findings.

Elevated ANA titers are often present in children with active SLE. This is an excellent screening tool, although ANA can be found without any disease or can be associated with rheumatic and other conditions (Table 148–3). Levels of anti–double-stranded DNA, which are more specific for lupus, reflect the degree of disease activity. Serum levels of total hemolytic complement (CH_{50}), C3, and C4 are decreased in active disease and provide a second measure of disease activity. Anti-Smith antibody, found specifically in patients with SLE, does not measure disease activity. When present, anti-SSA and anti-SSB antibodies are rarely associated with Sjögren syndrome. Many autoantibodies can be found (Table 148–4). Hypergammaglobulinemia is also frequent.

Treatment.

The treatment regimen depends on the affected target organs and disease severity. Patients are treated to support clinical well-being, using serologic markers of disease activity as guidelines, including serum complement levels. Nonsteroidal anti-inflammatory agents, used to treat arthralgia and arthritis, are used with caution because patients with SLE are more susceptible to hepatotoxicity. The antimalarial agent hydroxychloroquine may be used to treat mild manifestations, including skin

lesions, fatigue, arthritis, and arthralgia.

Patients with thrombosis and antiphospholipid antibodies or a lupus anticoagulant should receive anticoagulant medication at least until SLE is in remission. The length of therapy is controversial. Low molecular weight heparin is the anticoagulant of choice; however, warfarin can also be used.

Corticosteroids have been demonstrated to control symptoms and autoantibody production in SLE. Treatment with corticosteroids has improved kidney disease and the rate of survival. Corticosteroids, however, can make diagnosis of tuberculosis difficult; all patients should have PPD and control skin tests, when possible, before corticosteroids are initiated. The optimal dose and route of administration of corticosteroids are controversial. Patients with systemic disease are often started on 1–2?mg/kg/24?hr of oral prednisone in divided daily doses. When complement levels increase to within the normal range, the dose is carefully tapered over 2–3 yr to the lowest effective dose. One method is to use alternate-day high-dose corticosteroids to prevent the adverse effects of daily corticosteroid administration. Severely ill patients may require pulse intravenous corticosteroid therapy (30?mg/kg/dose, maximum 1?g, given over 60?min once per day, for 3 days). Intermittent high-dose intravenous therapy in combination with low-dose daily oral corticosteroids has been used as an alternative regimen in some centers. Adverse effects of corticosteroids include hypertension, gastritis, cataracts, osteopenia, and cushingoid body habitus.

TABLE 148-2 -- 1982 Revised Criteria for Diagnosis of Systemic Lupus Erythematosus

Criterion*	Definition
Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Rash as a result of unusual reaction to sunlight (elicited by patient history or physician observation)
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion
	or
	Pericarditis—documented by ECG or rub or evidence of pericardial effusion
Renal disorder	Persistent proteinuria > 0.5 g/day or > 3-plus (+ + +) if quantitation not performed
	or
	Cellular casts—may be red blood cell, hemoglobin, granular, tubular, or mixed
Neurologic disorder	Seizures—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance)
	or
	Psychosis—in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance)
Hematologic disorder	Hemolytic anemia—with reticulocytosis
	or
	Leukopenia—< 4,000/mm^3 total on two or more occasions
	or
	Lymphopenia—< 1,500/mm^3 on two or more occasions
	or
	Thrombocytopenia—< 100,000/mm^3
Immunologic disorder	Positive LE cell preparation
	or
	Anti-DNA antibody to native DNA in abnormal titer
	or
	Anti-Sm—presence of antibody to Sm nuclear antigen
	or
	False-positive serologic test result for syphilis known to be positive for at least 6 mo and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any time and in the absence of drugs known to be associated with “drug-induced lupus syndrome”

From Tan EM, Cohen AS, Fries JF, et al: The 1982 revised criteria for the classification of systemic lupus erythematosus. Arthritis Rheum 1982;25:1271–7.

A proposed modification deletes the positive LE cell preparation from the immunologic disorder criteria and substitutes the presence of antiphospholipid antibodies for a biologic false-positive test for syphilis (Hochberg MC: Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus. *Arthritis Rheum* 1997;40:1725).

**The proposed classification is based on 11 criteria. For the purpose of identifying patients in clinical*

studies, a person shall be said to have systemic lupuserythematosus if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation.

Patients with severe disease may require cytotoxic therapy. Pulse intravenous cyclophosphamide has maintained renal function and prevented progression in patients with lupus nephritis, particularly diffuse proliferative glomerulonephritis; however, the optimal length of therapy remains controversial. Cyclophosphamide has been used to treat vasculitis, pulmonary hemorrhage, and CNS disease refractory to corticosteroids. Azathioprine has been used to prevent renal disease progression. Little is known about the long-term sequelae of cytotoxic medications, particularly in children. Adverse effects include secondary infections, gonadal dysfunction, and possibly increased risk of malignancies later in life. Prepubertal children, compared with those who have entered puberty, may be at less risk for subsequent gonadal dysfunction from cytotoxic agents.

Other interventions are being proposed for the treatment of SLE. The role of methotrexate, cyclosporine, and mycophenolate mofetil remains undetermined. Hormonal therapy and

TABLE 148-3 -- **Conditions Associated with Antinuclear Antibodies (ANAs)**

Drug-induced lupus	Infectious mononucleosis
Juvenile arthritis	Chronic active hepatitis
Juvenile dermatomyositis	Hyperextensibility
Vasculitis syndromes	

autologous and cord stem cell marrow transplantation for patients with severe, persistent disease are undergoing clinical trials in adult patients with SLE. Biologic agents that target cytokine production are also being developed and studied.

The extent of renal involvement may be out of proportion to findings on urinalysis, and renal biopsy for staging can help determine whether an immunosuppressive agent such as cyclophosphamide needs to be added to a corticosteroid regimen (see Chapter 505). Biopsy findings according to the World Health Organization classification correlate with morbidity and mortality. Class I is defined as the absence of abnormalities on light microscopy, immunofluorescence studies, and electron microscopy. Class IIA shows minimal immunoglobulin and complement deposition in mesangium on immunofluorescence and is associated with good prognosis for renal function. Class

TABLE 148-4 -- **Autoantibodies Found in Systemic Lupus Erythematosus**

Antibody	Manifestation
Coombs antibodies	Hemolytic anemia
Antiphospholipid antibodies	Antiphospholipid antibody syndrome
Lupus anticoagulant	Coagulopathy
Antithyroid antibodies	Hypothyroidism
Antiribosomal P antibody	Lupus cerebritis

IIB (mesangial glomerulonephritis) shows increased lymphocytic infiltration of the mesangium and has a variable prognosis; it occasionally progresses to more extensive renal involvement. Class III (focal and segmental proliferative glomerulonephritis) is characterized by focal, segmental proliferation of cells near capillaries, with necrosis and lymphocytic infiltration, and is often associated with chronic renal disease. Class IV (diffuse proliferative glomerulonephritis) shows a majority of each glomerulus affected by cellular infiltration, mesangial cellular proliferation, and crescent formation corresponding to scarring and has been correlated with increased risk for developing end-stage renal disease in adulthood; intravenous pulse cyclophosphamide can decrease this risk. Class V disease (membranous glomerulonephritis) shows thickened capillary walls on light microscopy and subepithelial deposits on electron microscopy along the basement membrane. These changes have been associated with proteinuria, which can occur with the other types of lupus nephritis, and variable chronic renal disease, often poorly responsive to treatment.

The most important aspect of management of SLE is meticulous and frequent re-evaluation of patients. This includes clinical and laboratory evaluation, especially for renal and serologic flare of disease. Prompt recognition and treatment of disease flare is essential to patient outcome. Lupus is a lifelong illness, and patients must be monitored indefinitely.

Complications and Prognosis.

Childhood SLE was initially viewed as a uniformly fatal disease. With progress in diagnosis and treatment, the 5-yr survival rate is greater than 90%. However, a significant proportion of patients die later of the disease. Major causes of death in patients with SLE currently include infection, nephritis, CNS disease, pulmonary hemorrhage, and myocardial infarction; the latter complication may be a result of chronic corticosteroid administration in the setting of immune complex disease.

148.1 Neonatal Lupus

Lupus in newborns results from maternal transfer of IgG autoantibodies, usually anti-Ro, between the 12th and 16th wk of gestation. Manifestations include congenital heart block, cutaneous lesions, hepatitis, thrombocytopenia, neutropenia, and pulmonary and neurologic disease. Cutaneous lesions occur after ultraviolet exposure at about 6 wk of life and last 3–4 mo. The rash most frequently occurs on the face and scalp; 25% of rashes scar. Treatment is supportive. Most manifestations resolve, although congenital heart block is permanent and often requires cardiac pacing, either after birth or, when detected and severe, antenatally. Even infants of mothers with lupus who are asymptomatic may have slightly prolonged PR intervals. Cardiomyopathy is a rare serious sequela, sometimes requiring heart transplantation.

Neonatal lupus must be distinguished from **infantile multisystem inflammatory disease**, a rare syndrome characterized by fever, rash, arthropathy, chronic meningitis, seizures, uveitis, and lymphadenopathy. This syndrome is difficult to treat and usually requires long-term immunosuppression.

Chapter 149 - Juvenile Dermatomyositis

Lauren M. Pachman

Juvenile dermatomyositis (JDM), the most common of the pediatric inflammatory myopathies, is a systemic vasculopathy with characteristic cutaneous findings and focal areas of myositis resulting in progressive proximal muscle weakness that is responsive to the prompt institution of immunosuppressive therapy.

Etiology.

The disease appears to be triggered by an antigen driven response in the genetically susceptible child who is positive for the HLA antigen DQA1*0501. The putative agent may be associated with episodic disease, because clusters of new cases of JDM have been observed. Enterovirus (coxsackievirus B) has been implicated in new-onset JDM, both in the United Kingdom by RNA detection and in the United States by elevation in complement-fixing and neutralizing antibody titers. JDM has also followed documented infection with group A *Streptococcus.* Case-control serologic investigations have not substantiated an association of JDM with other potential infectious triggers such as *Toxoplasma gondii,* herpes simplex virus, or hepatitis B. In addition, the gene expression profiles in muscle biopsies from untreated children with JDM (positive for DQA1*0501) show a marked up-regulation of genes induced by interferon (IFN)-a and IFN-ß, supporting the concept of an antigen driven immune response.

Epidemiology.

The incidence of JDM is 3.2/million children/yr, but there may be some annual variation, which is apparently similar for all racial groups, although 73% of the cases are in whites. The average age of onset is 6.7 yr; children with disease onset before age 7 yr may have a milder course. In the United States, the overall ratio of girls to boys is 2.3:1. Multiple cases of myositis in a kindred are rare, and familial autoimmune disease is not increased in JDM, in contradistinction to juvenile rheumatoid arthritis. Reports of seasonal association have not been verified, although clusters of new cases occur. The prevalence of JDM is difficult to determine because persistent symptoms such as mild skin involvement and loss of range of motion are often disregarded. The long-term consequences of low levels of disease activity have yet to be defined.

Pathogenesis.

Disease susceptibility appears to be associated with the class II HLA antigen DQA1*0501, which is found in more than 80% of JDM children in the United States. A chronic disease course appears to be associated with a substitution of an A for a G in the -308 promoter region of the gene for TNF-a. Children who have the TNF-a-308A allele, compared to JDM children without this allele, frequently have increased cellular production of TNF-a, a chronic disease course, requiring immunosuppressive therapy for >36 mo, as well as an increased frequency of pathologic calcifications.

Endothelial cell activation by the putative antigen and/or immune complexes is accompanied by complement activation and release of von Willebrand factor antigen from the damaged endothelium. Occlusion of capillaries and arterioles with local infarction of tissue, perifascicular atrophy, and a mononuclear cellular infiltrate confirm the histologic diagnosis of JDM. New-onset, untreated JDM has four times as many CD56 natural killer (NK) cells in the muscle as in matched peripheral blood, suggesting a role for NK cells. Other T-cell subsets are also represented in diseased muscle; the number of monocytes/macrophages (CD14) correlates with serum levels of neopterin, a macrophage-derived T-cell factor. Extensive fibrosis leads to loss of range of motion. In affected skin, the epidermis thins and the dermis demonstrates edema and vascular inflammation.

Clinical Manifestations.

Disease onset is often insidious; constitutional symptoms of fatigue, low-grade fever, weight loss, and irritability are common as are arthralgia and abdominal pain. The characteristic rash appears first in 25% of cases, or at the same time that weakness is recognized in another 50% of children. The rash is prominent in sun-exposed areas, and proximal muscle weakness is usually recognized after a median of 2 mo. Periorbital violaceous (heliotropic) erythema (**heliotrope eyelids**) may cross the nasal bridge (Fig. 149–1). Periorbital edema may be present; edema may be generalized. The rash may involve the upper torso, the extensor surfaces of the arms and legs, the medial malleoli of the ankles, and the buttocks. Facial edema and eyelid telangiectasia occur in 50–90% of cases. Partial baldness is a consequence of chronic scalp inflammation. The skin over the metacarpal and proximal interphalangeal joints may be hypertrophic and reddish pink (**Gottron papules**) during active disease, with a papular, alligator skin–like appearance (Fig. 149–2), which evolves into atrophic colorless bands. Children with an initial amyopathic form of JDM (with the rash only), if not appropriately treated, may develop myositis and subsequent calcinosis later in their disease course. Diffuse vasculopathy (e.g., nailbed telangiectasia, infarction of oral epithelium and skinfolds, digital or gastrointestinal ulceration) is clearly associated with more severe disease; healing may be accompanied by hyperpigmentation or vitiligo.

The onset of proximal muscle weakness is insidious and difficult to recognize. It is often detected by difficulty in climbing stairs, combing hair, or standing from a sitting position. The child cannot rise unassisted from the floor without "climbing up the body" (**Gowers sign**). Neck flexor weakness (inability to raise the head from the bed) or abdominal muscle weakness (inability to perform a sit-up) identifies inflamed muscles that are often tender on compression. Derangement of upper airway function can be detected by hoarseness, a nasal quality to the speech, or difficulty in handling secretions. Dysphagia is a severe prognostic sign and should prompt immediate aggressive therapeutic intervention. Complaints of constipation reflect impaired gastrointestinal (GI) smooth muscle function, and abdominal pain or diarrhea may indicate occult GI bleeding, which can progress and be life threatening. Cardiac involvement with conduction abnormality is frequent at diagnosis; dilated cardiomyopathy has been reported. Lymphadenopathy is not uncommon.

Children with antibody to the polymyositis/scleroderma (Pm/Scl) antigen often have bambooing of the digits with loss of

Figure 149-1 The facial rash of juvenile dermatomyositis. There is erythema over the bridge of the nose and malar areas, with violaceous (heliotropic) discoloration of the upper eyelids.

Figure 149-2 The rash of juvenile dermatomyositis. The skin over the metacarpal and proximal interphalangeal joints may be hypertrophic and pale red (Gottron papules).

cutaneous elasticity, similar to scleroderma. **Mechanic's hands**, with thickened skin, cuticle overgrowth, and range losses, are indicators of a subset of refractory inflammatory myopathy more common in adults, who may have severe lung involvement and characteristic circulating antibody (Jo–1) to tRNA synthetase.

Less frequent findings include hepatosplenomegaly, retinitis, iritis, central nervous system (CNS) involvement with seizures and depression, and evidence of renal impairment. Association with malignancy at disease onset is observed in adults with dermatomyositis, but not in children.

Diagnosis.

The characteristic rash facilitates early diagnosis but should be differentiated from other connective tissue diseases such as systemic lupus erythematosus, scleroderma, or mixed connective tissue disease by both the specific antibody tests and clinical findings associated with each of these disorders. Careful examination of the nailfold capillaries usually documents periungual avascularity with capillary dropout. Those capillaries that remain are usually dilated and have the characteristic terminal bush formation (Fig. 149–3).

If the initial symptom is restricted to weakness, other causes of myopathy should be considered, including acute polymyositis

Figure 149-3 Nailfold capillary pattern in rheumatic diseases. *A*, Normal nailfold capillary pattern in a healthy child, with a homogeneous distribution and uniform appearance of capillary loops. *B*, The

nailfold capillary pattern in a child with juvenile dermatomyositis that shows dropout of capillary end-loops, resulting in a wide band of avascularity. Dilated, tortuous capillaries are also seen, some with terminal bush formation that is found in patients with juvenile dermatomyositis, with scleroderma, and with Raynaud phenomenon that may progress to scleroderma.

associated with influenza B infection, the muscular dystrophies (including Duchenne and Becker muscular dystrophies), myasthenia gravis, Guillain-Barré syndrome, and endocrine or metabolic disorders. Infections associated with muscular symptoms, such as poliomyelitis, trichinosis, or toxoplasmosis, also should be considered. Blunt trauma and crush injuries may lead to transient rhabdomyolysis with myoglobinuria. Other events associated with myositis in children include vaccinations, drugs, growth hormone, and bone marrow transplantation, in which graft versus host myositis occurs as a component of immune activation (see Chapter 127).

Laboratory Findings.

Elevated serum levels of muscle-derived enzymes (e.g. creatine kinase, aldolase, serum glutamic-oxaloacetic transaminase, and lactic acid dehydrogenase) reflect the leaky muscle membranes. Antinuclear antibody (ANA) with a speckled pattern (unknown specificity) is present in more than 60% of children, whereas tests for antibodies to SSA, SSB, Sm, RNP, and DNA are negative. Other myositis-specific antibodies, which rarely occur in children, such as to signal recognition particle (SRP), identify children with a protracted disease course, often complicated by pulmonary interstitial fibrosis. Antibodies to Pm/Scl identify a subgroup of myopathies that may not completely resolve and may have cardiac involvement with tachycardia and elevated troponin levels. The erythrocyte sedimentation rate is usually normal, with a Coombs-negative anemia, and the rheumatoid factor is negative.

Indicators of immunologic activation in JDM include increased percentage of peripheral blood CD19 B cells (despite being lymphopenic), and an elevated CD4:CD8 ratio, with decreased CD8 cells, which home to the muscle. In about two thirds of cases there is an increase in levels of von Willebrand factor antigen (vWF:Ag, adjusted for blood group ranges), which is released by damaged endothelial cells, or increased neopterin, which is released by activated macrophages.

MRI using T2 weighted images and fat suppression (Fig. 149–4) can localize the active site of disease for diagnostic muscle biopsy and electromyogram, both of which are nondiagnostic in 20% of instances if not directed by MRI. Extensive rash and abnormal MRI findings are not uncommon despite normal serum levels of muscle-derived enzymes. Muscle biopsy often demonstrates evidence of disease activity and chronicity that is not suspected from the levels of the serum enzymes alone.

A rehabilitation cookie swallow can document significant palatorespiratory dysfunction and an unprotected airway. Pulmonary function testing of the diffusion capacity of the lung for carbon monoxide (D_{lco}), which can be used for children older than 6 yr, detects decreased respiratory muscle strength as well as alveolar fibrosis associated with other connective tissue diseases. Active disease is frequently associated with decreased bone density with abnormal findings on densitometry and low osteocalcin and vitamin D levels. Calcinosis is detected by plain radiographs.

Treatment.

All children with JDM should use a sunscreen (free of *p*-aminobenzoic acid) that provides maximal protection against ultraviolet A and B, even in winter. Vitamin D, at the dose appropriate for weight, with a diet sufficient in calcium, repairs osteopenia and decreases the frequency of bone fracture.

The aid of an experienced pediatric rheumatologist is essential in assessing the need for therapeutic intervention. Children with only mild cutaneous findings, normal immune and serologic markers of disease activity, and a negative family history of color blindness may take hydroxychloroquine (maximum dose of 5?mg/kg/24?hr), with a low daily dose (about 1?mg/kg) of oral corticosteroids. These children should be monitored for the development of muscle involvement by careful physical examination which assesses pediatric muscle strength, as well as the laboratory testing for elevation of immune markers and serum muscle enzymes. If needed, a repeat MRI may identify new areas of muscle involvement.

With minimal muscle damage, oral corticosteroids (prednisone, 1–2?mg/kg/24?hr) may suffice. However, prompt institution of high-dose intermittent intravenous methylprednisolone therapy may rapidly normalize the muscle enzymes, and additional therapy is used if the indicators of inflammation (percentage of CD19 B cells, neopterin, vWf:Ag) remain elevated. Inhibitors of gastric acid secretion are usually also administered to minimize gastric bleeding. Pulse intravenous corticosteroid therapy (30?mg/kg/24?hr of methylprednisolone, not greater than 1?g daily, for 3 days) usually is initially given; thereafter, the frequency of methylprednisolone administration ranges from three times per week to once each week until all the indicators of inflammation normalize. Low-dose oral prednisone

Figure 149-4 An MRI scan with T2 weighted image with fat suppression of the proximal muscle of the lower extremities of a child with juvenile dermatomyositis with normal muscle enzymes. There is focal inflammatory myopathy. The white areas reflect the inflammatory response in involved muscle; those areas that are darker are more normal. Identification of the involved areas by MRI aids in directing the location of the muscle biopsy or electromyogram.

(0.5?mg/kg/24?hr) is given on non-intravenous methylprednisolone days. Methotrexate can be added (15–20?mg/m^2) if laboratory values fail to normalize as rapidly as expected, but should be given in conjunction with folic acid (1?mg/24?hr). Cyclophosphamide (500?mg/m^2 , given with mesna for bladder protection) is considered for children unresponsive to intravenous methylprednisolone and methotrexate. The associated immunosuppression may result in decreased levels of IgG (<300?mg/dL) and replacement immunoglobulin (0.4?g/kg/mo) may be required to help prevent infections. High-dose intravenous immunoglobulin may initially diminish cutaneous symptoms, but it is not clear that the disease course is altered. Cyclosporine has been successful in some resistant cases and appears to be helpful for primarily cutaneous involvement. Inhibitors of TNF-a have been tried in children with chronic disease with limited success, but may help those with limited range of

motion.

Children with dysphagia require a soft diet or nasogastric feedings, if necessary, until treatment restores a functional, protected airway. In rare cases, a respirator and tracheostomy or even extracorporeal membrane oxygenation are required. Absorption of calories and medication may be impaired by extensive GI vasculitis, requiring parenteral hyperalimentation and intravenous administration of drugs. Renal damage secondary to massive creatinine excretion can be averted by appropriate intravenous hydration.

Physical and occupational therapy provide passive stretching early in the disease course and, once active inflammation has resolved, direct reconditioning of muscles to regain strength and range of motion. Bed rest is not indicated; weight bearing improves bone density. Social work services may help facilitate adjustment to the frustration of physical impairment in a previously active child.

Complications.

Aspiration pneumonia is a frequent major complication associated with unrecognized impairment in swallowing fluids. Progressive bowel infarction can lead to perforation and death. Depression and mood swings are part of the disease spectrum of CNS involvement and may be accentuated by corticosteroid administration.

Calcinosis is present in about 20% of patients at diagnosis and is associated with increased morbidity and mortality. It is probably a consequence of disease chronicity, fostered by either delay in initiation of therapy or insufficient suppression of inflammation. The calcium deposits form primarily in subcutaneous tissue and fascia; they may drain a white cheesy material and resolve or serve as a nidus for infection (most frequently staphylococcal), which can progress to septicemia and death. Aggressive therapy at the time of diagnosis may be associated with decreased frequency of this unwelcome disease consequence.

Partial lipodystrophy develops in more than 10% of cases of chronic JDM. It is also associated with the TNF-a-308a allele and is characterized by (1) loss of subcutaneous fat on the extremities, giving a hypermuscular appearance; (2) acanthosis nigricans; (3) weakened abdominal muscles resulting in a potbelly appearance; and (4) abnormal glucose and lipid metabolism. Girls may lose their menses, and sterility may result if the onset of JDM is before puberty.

Prognosis.

Before the advent of corticosteroids, one third of affected children died and another one third were disabled. The mortality rate is currently about 1%. Although the disease is classified as “chronic,” little is known about the consequences of persistent vascular inflammation. The period of active symptoms has decreased from about 3.5 yr to less than 1.5 yr with more aggressive immunosuppressive therapy. Unlike many adults with inflammatory myopathies, children with JDM appear able to repair their vasculature and muscle damage, but follow-up biopsy studies await analysis. The impact of partial lipodystrophy on adult morbidity is not known. Overall, with newer tests to monitor inflammation and disease activity and guide more aggressive therapy, the prognosis for this illness has markedly improved.

Chapter 150 - Scleroderma

Michael L. Miller

Scleroderma, a chronic disease of unknown cause, is characterized by fibrosis affecting the dermis and arteries of the lungs, kidneys, and gastrointestinal (GI) tract. Antinuclear antibodies (ANAs) specific for topoisomerase 1 (SCL70) and the centromere are found in many patients, which suggests that autoimmune processes play a role in pathogenesis. Scleroderma is classified according to the pattern of skin and internal organ involvement (Box 150–1).

Box 150-1. Classification of Scleroderma

SYSTEMIC SCLEROSIS

- Diffuse: systemic widespread skin fibrosis, including proximal limbs, trunk, and face; early internal organ involvement
- Limited (CREST): systemic distal skin involvement, often face, with late, if any, internal organ involvement
- Overlap: sclerodermal skin changes with features of other connective tissue disorders

LOCALIZED SCLERODERMA

- Morphea
- Generalized morphea
- Linear scleroderma
  - On face, forehead, or scalp (*coup de sabre*)
  - On extremity

EOSINOPHILIC FASCIITIS SECONDARY FORMS

- Drug induced
- Chemically induced

PSEUDOSCLERODERMA

Epidemiology.

Scleroderma is a rare disease. The peak age at onset for systemic sclerosis is 30–50 yr, with a female:male ratio of 3:1. Children represent fewer than 10% of all cases. The cause is unknown but appears to involve injury to vascular endothelium. Rare cases have been reported after exposure to polyvinyl chloride, bleomycin, and pentazocine. Reports of scleroderma in adult women after breast implants may reflect nonrelated conditions, because medical devices (e.g., ventriculoperitoneal shunts) containing silicone have been implanted for many years without reports of similar complications. In children, localized scleroderma is more common than systemic sclerosis. The two forms usually do not overlap.

Pathogenesis.

Scleroderma is associated with destruction of vascular endothelium and an increase in the basal lamina. During the initial stages of disease, lymphocytes, macrophages, mast cells, plasma cells, and eosinophils infiltrate the dermis. Factors released from activated platelets may play a role in Raynaud phenomenon and in triggering fibroblast proliferation that increases collagen synthesis, resulting in fibrosis of the dermis, subcutaneous fat, and sometimes muscle.

Studies suggest that a yet unidentified agent, or possibly subclinical graft versus host reaction from persisting cells of maternal origin, injures vascular endothelial cells, resulting in increased expression of adhesion molecules on their surfaces. These molecules entrap platelets and inflammatory cells, resulting in vascular changes of the type associated with such manifestations as Raynaud phenomenon, renovascular hypertension, and pulmonary hypertension. Recruitment of lymphocytes to areas of vascular damage may be the event that leads to specific autoantibody production in many patients. After these events, macrophages and other inflammatory cells appear to leave blood vessels and migrate into tissues affected in scleroderma. These cells secrete interleukin-1 (IL-1), causing platelets to release platelet-derived growth factor (PDGF). These and other molecules induce fibroblasts to reproduce and synthesize excessive amounts of collagen, resulting in fibrosis.

Clinical Manifestations.

Raynaud phenomenon, resulting from digital arterial spasm, is often the earliest manifestation and may precede extensive skin and internal organ involvement by months or years. Raynaud phenomenon, which is induced by exposure to cold, affects the fingers, toes, and occasionally the ears and the tip of the nose. It has three stages: pallor, cyanosis, and finally erythema. Two of three stages are considered sufficient for identifying this manifestation. Episodes can vary in duration from minutes to hours.

SYSTEMIC SCLEROSIS.

Systemic sclerosis often presents with a preliminary edematous phase that can last several months before chronic fibrosis develops. These early changes include puffiness around the fingers, on the dorsum of the hands, and sometimes on the face. An eventual decrease in edema is associated with tightening of the skin. Skin changes tend to spread proximally from the hands. Loss of subcutaneous tissue in the face can result in a small oral stoma with decreased distance between the upper and lower teeth when the mouth is opened wide (Fig. 150–1). Skin ulceration over pressure points, such as the elbows, may be associated with subcutaneous calcifications. Later, atrophic skin can become shiny and waxy in appearance. Loss of tissue at the fingertips may be associated with ulceration if Raynaud phenomenon is severe (Fig. 150–2). The distal phalanges may exhibit **acro-osteolysis,** or resorption of the distal tufts. The fingers take on a tapered appearance associated with tightened skin (**sclerodactyly**) and eventual development of secondary and often severe flexion contractures and limitation of motion (Fig. 150–3). As lesions spread proximally, flexion contractures in the elbows, hips, and knees may be associated with secondary muscle weakness and atrophy. Other chronic changes include epidermal thinning, hair loss, and decreased sweating. Hyperpigmented postinflammatory changes surrounded by atrophic depigmentation may give a salt-and-pepper appearance to some skin lesions. Over a period of years, remodeling of lesions sometimes results in focal improvement in skin thickening at the same time fibrosis extends elsewhere.

Pulmonary disease includes arterial and interstitial involvement and can vary from minimal disease to a progressive course that eventually results in decreased exercise tolerance, dyspnea at rest, and right-sided heart failure. Chest roentgenograms may appear normal early in the course. Evidence of early involvement may be found only by performing pulmonary function tests, including evaluation of oxygen diffusion by diffusion of carbon monoxide capacity (D_LCO). High-resolution CT may also detect changes associated with interstitial disease before they become apparent on chest roentgenograms.

Scleroderma can also affect other organs. Renal arterial disease can cause chronic or severe episodic hypertension. Esophageal dilatation caused by fibrosis can cause dysphagia.

Figure 150-1 Facial changes in a 16-yr-old boy with scleroderma. There is a small mouth with puckering of the lips, pinched nose, and hyperpigmentation of the neck. (From Uziel Y, Miller ML, Laxer RM: Scleroderma in children. *Pediatr Clin North Am* 1995;42:1177.)

Figure 150-2 Tiny digital pitting scars and loss of pulp space resulting from digital ischemia in a 15-yr-old boy with scleroderma. (From Uziel Y, Miller ML, Laxer RM: Scleroderma in children. *Pediatr Clin North Am* 1995;42:1178.)

Figure 150-3 Inability to make a full fist due to skin and soft tissue tightening in a 10-yr-old girl with scleroderma. (From Uziel Y, Miller ML, Laxer RM: Scleroderma in children. *Pediatr Clin North Am*

1995;42:1176.)

Dilated intestinal loops can result in malabsorption and failure to thrive. Cardiac fibrosis has been associated with arrhythmias, ventricular hypertrophy, and decreased cardiac function.

Scleroderma can present with less extensive involvement. In limited systemic scleroderma, children have less prominent fibrosis that is limited to the distal extremities, face, and neck. Telangiectasias may appear on the fingertips, face, chest wall, and inner surface of lips. The **CREST syndrome** refers to the manifestations of calcinosis, Raynaud phenomenon, esophageal involvement, sclerosis of the skin, and telangiectasias. Severe pulmonary hypertension develops in some patients with CREST syndrome.

MORPHEA AND LINEAR SCLERODERMA.

In localized scleroderma, the involvement is restricted to the skin; progression to systemic sclerosis is rare. In children with **morphea,** a form of localized scleroderma, lesions are typically discrete and may occur anywhere on the body but particularly on the face. Early inflammation is followed by indurated, depigmented, atrophic lesions. Children with **linear scleroderma** have lesions affecting the length of extremities; these lesions vary in size from several centimeters to the entire length of the extremity. Fibrosis in the dermis can sometimes extend to muscle, resulting in some instances in total loss of muscle tissue between the dermis and bone. Resulting leg-length discrepancies, joint flexion contractures (Fig. 150–4), or cosmetic deformities of the face, forehead, or scalp with scarring alopecia (coup de sabre) may require surgical intervention.

Diagnosis.

Scleroderma should be suspected in children who develop Raynaud phenomenon followed by skin changes suggestive of sclerodactyly. If Raynaud phenomenon is present for years before classic disease expression, ANA (particularly anti-SCL70) are typically found. Subclinical pulmonary fibrosis, suspected if decreased D_LCO is found on pulmonary function testing, may be confirmed by high-resolution CT. Nailfold capillaroscopy of patients with Raynaud phenomenon before progression of disease may reveal a loss of capillaries or abnormal capillary dilatation resulting from vasculopathy (see Fig. 149–3).

According to diagnostic criteria used in adults, the diagnosis of scleroderma requires the presence of the single major criterion (sclerodermatous skin changes proximal to the metacarpophalangeal or metatarsophalangeal joints) or two of the three minor criteria (Box 150–2). The evaluation in these patients should include pulmonary function tests, contrast studies of the upper GI tract to evaluate esophageal motility, and echocardiography to identify pulmonary arterial hypertension.

DIFFERENTIAL DIAGNOSIS.

Several conditions present with findings similar to those of scleroderma. Acrocyanosis, in which there is no associated pallor or reflex hyperemia, may be seen following pulmonary arterial hypertension, anorexia nervosa, or frostbite.

Diffuse finger swelling extending to the dorsum of the hands can be seen in Henoch-Schönlein purpura and with allergic reactions. Patients with juvenile rheumatoid arthritis usually have swelling in the fingers that is restricted to

Figure 150-4 Extensive morphea involving the entire left leg causing shortening and flexion contractures. The skin has a shiny appearance with patches of hyperpigmentation and vitiligo.

Box 150-2. Diagnostic Criteria of Scleroderma *

MAJOR CRITERION

Proximal scleroderma: typical sclerodermatous skin changes (tightness, thickening, and nonpitting induration, excluding localized forms of scleroderma) involving areas proximal to the metacarpophalangeal or metatarsophalangeal joints

MINOR CRITERIA

Sclerodactyly: sclerodermatous skin changes limited to digits

Digital pitting scars resulting from digital ischemia

Bibasilar pulmonary fibrosis not attributable to primary lung disease

From Subcommittee for Scleroderma Criteria of the American Rheumatism Association Diagnostic and Therapeutic Criteria Committee: Preliminary criteria for the classification of systemic sclerosis (scleroderma). Arthritis Rheum 1980;23:581.

*The diagnosis of scleroderma requires the

Criteria Committee: Preliminary criteria for the classification of systemic sclerosis (scleroderma). *Arthritis Rheum* 1980;23:581.

*The diagnosis of scleroderma requires the presence of the major criterion or two of the three minor criteria.

the joints. Flexion contractures in these patients are a result of chronic tendinitis without dermal involvement; therefore, the skin is not tight, compared with that of patients with scleroderma. Manifestations of graft versus host disease after bone marrow transplantation (see Chapter 127) include erythema affecting the face and distal extremities, sclerodermatous skin changes, hepatitis, and diarrhea.

In **Raynaud disease**, Raynaud phenomenon occurs without the subsequent development of skin or internal organ changes of scleroderma. Such patients usually do not have anti-SCL70 or other autoantibodies, and their Raynaud phenomenon does not worsen over time. Weakness, sometimes related to flexion contractures, in patients with skin changes suggestive of early scleroderma raises the possibility of juvenile dermatomyositis or overlap syndromes in which elements of several rheumatic diseases (e.g., systemic lupus erythematosus, dermatomyositis, arthritis, and scleroderma) may be present.

Patients with **eosinophilic fasciitis** develop changes similar to those in localized scleroderma. However, laboratory evaluation shows a striking eosinophilia, elevated erythrocyte sedimentation rate, and occasionally hypergammaglobulinemia. Full-thickness skin biopsy, which extends to and includes muscle fascia, shows a predominately eosinophilic inflammatory infiltration in the dermis and fascial tissues that confirms the diagnosis. Progression to systemic sclerosis is rare. Corticosteroid treatment often ameliorates or prevents progression of lesions. However, some patients develop severe contracting fibrosis involving the entire length of the extremities. Limited experience suggests that it may be possible in some cases to prevent this complication with the use of methotrexate.

Pseudoscleroderma comprises unrelated diseases characterized by patchy or diffuse cutaneous fibrosis without the other manifestations of scleroderma. Patients with phenylketonuria can develop such lesions as well as eczematous changes. **Scleredema of Buschke** is a transient disease of sudden onset often following a febrile illness (especially streptococcal infections) in which patchy sclerodermatous lesions occur on the neck and shoulders, often extending to the face, trunk, and down the arms. These findings usually resolve spontaneously within several months.

Laboratory Findings.

Inflammation early in systemic disease may be reflected by anemia and sometimes eosinophilia. Immunoglobulin levels may be nonspecifically elevated. ANAs are often present, with a speckled or nucleolar pattern. If present, anti-SCL70, which is specific for topoisomerase 1, and anticentromere autoantibodies are strongly suggestive of a diagnosis of scleroderma. Autoantibodies usually found in systemic lupus erythematosus (anti-DNA) or mixed connective tissue disease (anti-ribonucleoprotein) suggest the presence of an overlapping syndrome. In the early phase of the disease, levels of von Willebrand factor antigen, a marker for vascular endothelial damage, may be elevated. In localized scleroderma, laboratory abnormalities are usually restricted to positive ANA (with anti-SCL70 and anticentromere antibodies much less common than in systemic sclerosis) and, on occasion, eosinophilia.

Treatment.

Although there is no specific treatment, immunosuppressive agents, including methotrexate and corticosteroids, in the early stages of the disease may be helpful in curbing inflammation. However, corticosteroids later in the course of the disease do not appear to be effective and may exacerbate hypertension. Additional treatment includes physical and occupational therapy to improve flexion contractures and maintain muscle strength, and spring-loaded splints in selected patients.

If Raynaud phenomenon persists despite local measures (e.g., keeping hands warm during cold exposure with Mylar or sheepskin gloves), therapy with calcium channel blockers (e.g., nifedipine, amlodipine besylate), angiotensin-converting enzyme inhibitors (e.g., captopril, enalapril), and topical vasodilators (e.g., nitroglycerin paste) may be successful in preventing or ameliorating fingertip ulcerations. Vascular compromise threatening to lead to gangrene and autoamputation of the distal digits may respond to parenteral administration of prostaglandin E_1 (alprostadil).

Complications.

Raynaud phenomenon can become severe enough to lead to early gangrenous changes with the threat of autoamputation of the digits. Arterial disease can also cause esophageal rupture, renovascular hypertensive crises, and pulmonary arterial hypertension with cor pulmonale. Chronic pulmonary insufficiency can result from pulmonary parenchymal disease and pulmonary arterial hypertension. Gastrointestinal involvement can result in malabsorption and failure to thrive. Renal disease and chronic pulmonary arterial hypertension can lead to death.

Prognosis.

The course of scleroderma is variable, and findings at presentation are not predictive. Some patients stabilize after several years and have no new skin or visceral involvement. Others show unrelenting progression of disease, with death, either in childhood or later in life, resulting from end-stage pulmonary, cardiac, or renal vascular disease.

Chapter 151 - Behçet Disease

Abraham Gedalia

Behçet disease, a multisystem disorder originally described as recurrent oral and genital ulceration associated with relapsing iritis or uveitis, is often characterized by cutaneous, arthritic, neurologic, vascular, and gastrointestinal manifestations. Fever, orchitis, myositis, pericarditis, nephritis, splenomegaly, and amyloidosis are rare associated manifestations. The disease is commonly reported in the Mediterranean basin and Asia and is relatively rare in Europe and the United States. The condition is uncommon in children, who account for only an estimated 5% of all cases.

The *etiology* of Behçet disease is unknown, although an association with HLA-B5 and HLA-B51 is clear. A few cases of transient neonatal Behçet disease in offspring of mothers with Behçet disease have been described, suggesting that an antibody-mediated immune process may have a role in the pathogenesis. The basic pathologic lesion is vasculitis of small- and medium-sized arteries with cellular infiltrations leading to fibrinoid necrosis and narrowing and obliteration of the vessel lumens. Necrotizing and granulomatous inflammation of a large vessel such as the aorta or pulmonary artery also may occur.

The *clinical course* is highly variable, with recurrent exacerbations and disease-free intervals of uncertain duration. Painful oral ulcers, usually 2–10?mm in diameter with surrounding erythema, develop over the oronasal cavity and upper airway in all patients, persist for days to weeks, and then heal without scarring. These necrotic ulcers may occur singly or in crops. Genital ulcers occur in most patients and follow a parallel course but may heal with scars. Skin manifestations occur in most patients and include erythema nodosum, pseudofolliculitis, papulopustular lesions, and acneiform nodules. Cutaneous pathergy occurs as an erythematous sterile pustule after 24–48?hr at a needle-prick skin site. Ocular manifestations, including anterior or posterior uveitis and retinal vasculitis, occur less frequently in children than in adults but are more severe in the pediatric population and may progress to blindness. Arthritis is common and is usually acute, recurrent, asymmetric, and polyarticular, involving the large joints. Central nervous system abnormalities such as meningoencephalitis, cranial nerve palsies, and psychosis usually occur later in the

course of the disease and indicate a poor prognosis.

Laboratory findings are not diagnostic, although the finding of HLA-B5 or HLA-B51 support the diagnosis.

Treatment is based on anecdotal reports. A wide range of drugs has been used, including systemic corticosteroids, colchicine, chlorambucil, azathioprine, and cyclosporine. Colchicine has been demonstrated to be effective, showing higher efficacy in children than in adults, especially for oral ulcers, skin rash, joint symptoms, and occasionally eye disease. Recently, thalidomide has been reported to be a highly effective and useful therapeutic option for severe oral and genital ulceration that is unresponsive to other therapies. Another potentially important modality is anti–tumor necrosis factor-a therapy, which may also have a role in the management of Behçet disease.

Chapter 152 - Sjögren Syndrome

Abraham Gedalia

Sjögren syndrome is a chronic inflammatory autoimmune disease characterized by progressive lymphocytic and plasma cell infiltration of the salivary and lacrimal glands leading to xerophthalmia (dry eyes, or keratoconjunctivitis sicca), xerostomia (dry mouth), and associated connective tissue disease features. Sjögren syndrome typically occurs in women 35–45 yr of age, with a female:male ratio of 9:1. It is uncommon in the pediatric age group, although more than 50 cases in children have been reported. European criteria for the diagnosis of Sjögren syndrome in adult patients have been developed, and recently diagnostic criteria in children have been proposed.

Clinical manifestations are related to exocrine disease of the epithelial surfaces of the eyes, mouth, nose, larynx and trachea, vagina, and skin, leading to the common symptoms of photophobia, burning and itching eyes, and blurred vision; painless unilateral or bilateral enlargement of the parotid glands; decreased sense of taste; dental caries; dysphagia; fissured tongue; and angular cheilitis. Subjective symptoms of xerostomia are less frequent among juvenile cases, indicating that Sjögren syndrome is a slowly progressive disease. Additional manifestations may include a decreased sense of smell and epistaxis; hoarseness; chronic otitis media; and internal organ exocrine disease involving the lungs, hepatobiliary system, pancreas, gastrointestinal tract, and kidneys.

Non-exocrine disease manifestations of Sjögren syndrome may be related to inflammatory vascular disease (in skin, muscle and joints, serosae, peripheral and central nervous system), noninflammatory vascular disease (Raynaud phenomenon), mediator-induced disease (hematologic cytopenias, fatigue, and fever), and autoimmune endocrinopathy (thyroiditis). Because monoclonal B-lymphocyte disease originates chiefly from lymphocytic foci within salivary glands or from parenchymal internal organs, lymphoproliferative forms of Sjögren syndrome occur in adults with potential lymphoid malignancy. Parotitis at onset is much more frequent in children than in adults with Sjögren syndrome. However, positive antinuclear antibodies and articular manifestations are significantly more frequent in adults.

Sjögren syndrome can occur as an isolated disorder, referred to as **primary Sjögren syndrome**, or as a secondary form in association with other rheumatic disorders.

Most commonly it accompanies systemic lupus erythematosus or mixed connective tissue disease, and only rarely is it associated with juvenile rheumatoid arthritis. It precedes the associated autoimmune disease by years in half the cases. Maternal Sjögren syndrome can be an antecedent to the neonatal lupus syndrome.

The *diagnosis* is based on clinical features supported by biopsy of the lip or glands demonstrating foci of lymphocytic infiltration, cryoglobulinemia, elevated erythrocyte sedimentation rate, hypergammaglobulinemia, positive rheumatoid factor, and the presence of antibodies to Ro/SSA and La/SSB. A recent study found that anti-a-fodrin autoantibodies are a useful diagnostic marker for juvenile Sjögren syndrome. Ocular tearing may be evaluated by performing **Schirmer test**, which detects abnormal tear production (=5?mm of wetting of filter paper strip in 5?min). Imaging studies using magnetic resonance, technetium-99 scintigraphy, and sialography are useful in the diagnostic evaluation for Sjögren syndrome.

The *differential diagnosis* of Sjögren syndrome in children includes chronic recurrent parotitis, infectious parotitis, and tumors. In these conditions, sicca complex, rash, arthralgia, and antinuclear antibodies are usually absent.

Treatment is symptomatic, with use of artificial tears, oral lozenges, and fluids to limit the damaging effects of decreased secretions. Corticosteroids with or without immunosuppressive agents may be indicated for severe functional disorders and life-threatening complications.

Chapter 153 - Familial Mediterranean Fever

Abraham Gedalia

Familial Mediterranean fever (FMF) is an inherited disorder characterized by brief, acute, self-limited episodes of fever and polyserositis recurring at irregular intervals, as well as development of amyloidosis (see Chapter 154), which, if untreated, leads to end-stage renal failure. FMF appears to be transmitted as an autosomal recessive disease and essentially occurs among ethnic groups of Mediterranean origin, mainly Sephardic Jews, Turks, Armenians, and individuals of Arab descent. In these populations, the carrier frequency is estimated to be as high as one in five persons. Greeks, Hispanics, and Italians are less commonly affected. FMF is rare among Ashkenazi Jews, Germans, and Anglo-Saxons; other ethnic groups report only sporadic cases.

The onset of *clinical manifestations* occurs before age 5 yr in 63–68% of cases and before age 20 yr in 90% of cases. The onset may be as early as 6 mo of age. The typical acute episode lasts 1–4 days and includes fever and one or more symptoms of peritonitis manifested by abdominal pain (90%), arthritis or arthralgia (85%), and pleuritis manifested by chest pain (20%). Other serosal tissues such as the pericardium and tunica vaginalis testis are rarely affected. Erysipelas-like skin rash, myalgia, splenomegaly, scrotal involvement in boys, neurologic involvement, Henoch-Schönlein purpura, and hypothyroidism are other less common clinical manifestations. In about one third to one half of untreated patients with FMF, amyloidosis of AA (amyloid A) type develops and is manifested by proteinuria that progresses to nephrotic syndrome and renal failure over a period of months to several years. Death results from infection, thromboembolism, or uremia. Amyloidosis is common among Sephardic Jews and Turks and less common in Armenians. However, Armenians living in Armenia are reported to have a significantly higher incidence of amyloidosis than do their counterparts in North America, suggesting that environmental factors may also have a role.

The gene responsible for FMF was first mapped to a small interval on the short arm of chromosome 16p13.3, between the gene responsible for adult-onset polycystic kidney disease and the gene linked to Rubinstein-Taybi syndrome. The FMF gene, designated *MEFV*, was then identified and cloned by two independent groups, the international and the French consortia. *MEFV* is a new member of the RoRet gene family; it is approximately 10?kb with 10 exons that express a 3.7-kb transcript encoding a 781 amino acid protein known as **pyrin or marenostrin** that is expressed in myeloid cells. More than 29 mutations, most located in the last exon,

were discovered. It is unclear whether all are true disease-related mutations. The five most common mutations (M694V, V726A, M694I, M680I, and E148Q) were found in more than two thirds of tested Mediterranean FMF patients. Haplotypes and mutational analyses showed ancestral relationships among carrier chromosomes that have been separated for centuries. The most common missense mutation is methionine-694-valine (M694V), a mutation occurring in 20–67% of cases and associated with a higher disease severity index and a higher incidence of amyloidosis, followed by the valine-726-alanine (7–35%), which is associated with milder disease and a lower incidence of amyloidosis. This suggests that phenotypic differences may be related to different mutations. Cloning and identification of the FMF gene now make it possible to establish a diagnosis of FMF, especially in areas where the disease is rare and less familiar to physicians. Genetic screenings using restriction analysis PCR (polymerase chain reaction) systems are now available in some commercial genetic clinical laboratories. However, genetic laboratories usually screen for the 5–10 most common mutations, and rare mutations are missed. Therefore, the diagnosis of FMF is still based on clinical grounds, and genetic screening should be used as a confirmatory test.

The exact *pathogenesis* of the acute episodes of FMF is still not known, although some immunologic abnormalities have been reported. Of special interest is the finding of a C5a inhibitor (inactivating enzyme) deficiency in peritoneal and synovial fluids of patients with FMF. C5a is a fragment of complement, an anaphylatoxin, and a potent chemotactic agent. Normally, small amounts of C5a may be released into serosal cavities and are subsequently neutralized by the inactivating enzyme before they precipitate overt inflammation. One hypothesis is that a deficiency of C5a inhibitor, which is a consequence of pyrin dysfunction in patients with FMF, allows further accumulation of C5a, leading to the acute attack. Better understanding of pyrin function will shed light on its interactions with other proteins involved in the regulation of the inflammatory response.

Attacks of FMF can be *prevented* by prophylactic colchicine therapy at a dose of 0.02–0.03?mg/kg/24?hr (maximum of 2?mg/24?hr) in one or two divided doses. Colchicine therapy not only reduces the frequency of acute attacks but also greatly decreases the probability of development of amyloidosis and may lead to partial regression of existing amyloidosis. Colchicine therapy for FMF during pregnancy has not been reported to harm either the mother or her fetus.

Other conditions of periodic fever syndromes that have been recently recognized need to be considered in the differential diagnosis. There are at least three other separate periodic fever syndromes. **Hyperimmunoglobulin D periodic fever syndrome (HIDS)** is an autosomal recessive condition, reported mostly in families of European descent (Dutch, French), caused by mutations in the mevalonate kinase gene found on chromosome 12q24. Patients with this disorder manifest recurrent short episodes (>14 days) of fever associated with cervical lymphadenopathy, abdominal pain, rash, arthralgia/arthritis, occasional splenomegaly, increased level of acute-phase reactants, and elevated serum level of IgD (>100?U/mL). There is no known therapy for this condition, although glucocorticoids may be of some benefit. **Tumor necrosis factor (TNF)-receptor-associated periodic syndrome (TRAPS)** is a syndrome that was previously known by other names, including familial Hibernian fever, familial periodic fever, and autosomal dominant recurrent fever. This is a rare disorder that has been reported in a few families of Irish or Scottish ancestry and is caused by mutations in the gene encoding for type 1 TNF receptor protein, which has been mapped to chromosome 12p13. Patients with this condition manifest brief (4–6 days) intermittent febrile episodes associated with abdominal pain myalgias, and occasional occurrence of rash, conjunctivitis, and unilateral periorbital edema. Increased level of acute-phase reactants may be seen, but the most specific finding is a low serum level of soluble type 1 TNF receptor. Glucocorticoids may be helpful; using etanercept, a recombinant TNF receptor fusion protein, proved promising in a recent report. A new syndrome referred to as **periodic fever, aphthous stomatitis, pharyngitis, and adenitis (PFAPA)** is associated with arthralgia in some patients. The majority of patients respond to a single dose of oral prednisone (1–2?mg/kg). This syndrome usually develops before age 5 yr, with spontaneous resolution within 4–8 years. The etiology and the pathogenesis are still a puzzle, and it is not clear

whether this syndrome represents infectious or immunogenetic dysregulation entities. **REFERENCES**

Chapter 154 - Amyloidosis

Abraham Gedalia

Amyloidosis comprises a group of diseases characterized by extracellular deposition of insoluble fibrous **amyloid proteins** in various body tissues. The deposits are composed of seemingly homogeneous eosinophilic material that stains with Congo red dye and in polarized light demonstrates the pathognomonic apple-green birefringence of amyloid. Amyloid material is composed of microscopic fibrils that are biochemically heterogeneous, with at least 15 different types of protein compositions. However, all amyloid deposits contain an identical nonfibrillar component, **serum amyloid P.** Amyloid fibril deposition may have no apparent consequences, or it may ultimately interfere with organ function. Various disease states result from deposition of different types of amyloid material, and different patterns of tissue deposition result in various patterns of organ dysfunction. Regardless of the cause of amyloidosis, the clinical diagnosis is usually not established until the disease is far advanced.

Classifications of the amyloid proteins and the various amyloid diseases are complex. The **systemic amyloidoses** are multisystem diseases that correspond to clinical patterns of primary, secondary, familial, and dialysis-related amyloidosis. The **localized or organ-limited amyloidoses** are associated with aging and diabetes and occur in isolated organs such as endocrine glands, without evidence of systemic involvement. The most common types of amyloidosis are those related to primary idiopathic amyloidosis and multiple myeloma, with deposition of amyloid composed of pieces of monoclonal light chain of immunoglobulin (AL type). Secondary or reactive amyloidosis occurs in individuals with familial Mediterranean fever (FMF) and chronic inflammatory diseases related to another protein, amyloid A protein (AA type). Finally, a group of amyloid conditions, including those associated with aging (e.g., Alzheimer disease), and several rare familial types of amyloidosis are associated with other amyloid protein precursors.

Primary amyloidosis is extremely rare in children. Only secondary amyloidosis affects children in appreciable numbers, and it occurs in some individuals with FMF and after chronic inflammatory diseases, including juvenile rheumatoid arthritis (JRA), rheumatoid arthritis, ankylosing spondylitis, inflammatory bowel disease, chronic infections such as tuberculosis, and cystic fibrosis. AA protein isolated from amyloid found in these diseases is an N-terminus fragment of serum AA. Because serum AA protein acts as an acute-phase reactant, increased amounts resulting from chronic inflammation may provide an explanation for the occurrence of this form of secondary amyloidosis. Other inflammatory diseases such as lupus erythematosus or dermatomyositis, which are associated with shorter periods of inflammation, are not associated with secondary amyloidosis. Similar to FMF, secondary amyloidosis affects as many as 10% of children with JRA in some European countries but is rarely seen as a complication of seemingly similar disease in children in the United States and Canada. Reasons for this difference are unknown, although environmental factors may have a role. Secondary amyloidosis usually begins some years after the onset of inflammatory disease and is manifested by anemia, diarrhea, hepatosplenomegaly, proteinuria, and progression to nephrotic syndrome and eventual renal failure.

The *diagnosis* of amyloidosis is established by demonstration of amyloid in affected tissues. Renal biopsies are considered hazardous in the presence of amyloidosis because of potential bleeding. The spleen is often affected but is not a suitable site for biopsy. More accessible biopsy sites include the rectal mucosa and gingival tissue. A method of scintigraphy using serum amyloid P component has been described as a useful diagnostic tool and as a tool for monitoring the status of amyloidosis. Patients with JRA and secondary amyloidosis usually show elevated acute-phase reactants and high levels of immunoglobulins.

Unlike amyloidosis associated with FMF, amyloidosis associated with JRA does not respond to colchicine therapy but instead to chlorambucil, which reverses renal findings and prolongs life. Chlorambucil is associated with chromosome breakage and an unknown risk of subsequent malignancy. There is little experience with other cytotoxic agents and with the therapy for secondary amyloidosis associated with other conditions.

Amyloidosis is the most common serious complication of FMF, leading to end-stage renal disease. There is ethnic variability in the frequency of amyloidosis: among patients with FMF, amyloidosis occurs in up to 60% of Turks, 27% of Sephardic Jews, and 1–2% of Armenians living in the United States. Colchicine has been effective not only in controlling the attacks of FMF, but also in preventing the development of amyloidosis. A recent development is the discovery and cloning of the FMF gene. Phenotype-genotype correlation analysis of children with FMF revealed that patients with M694V homozygous genotype are at higher risk of developing amyloidosis. These children should be given colchicine for life.

Chapter 155 - Sarcoidosis

Margaret W. Leigh

Sarcoidosis, a chronic multisystem granulomatous disease of unknown cause, occurs most frequently in young adults but can occur during childhood.

Etiology.

The granulomas in sarcoidosis resemble those caused by certain microbial agents, such as mycobacteria and fungi, or by hypersensitivity to organic agents. These similarities have led to speculation that microbes or organic dusts may be inciting agents. However, despite extensive studies, the etiology remains obscure.

Epidemiology.

Sarcoidosis has a worldwide distribution involving all ethnic groups. In the southeastern United States, sarcoidosis occurs more frequently in African-Americans than in whites. Familial clustering of this disease has been observed and suggests a genetic predisposition; however, the mode of inheritance is unclear.

Pathology.

The noncaseating granulomatous lesions of sarcoidosis may occur in almost any organ of the body. Typically, the granulomas are not necrotic, and they contain epithelioid cells, macrophages, and giant cells in the center surrounded by a mixture of monocytes, lymphocytes, and fibroblasts. Activated lymphocytes and macrophages within the granulomas release various mediators including interleukin-1 (IL-1), IL-2, interferon, and other cytokines that are thought to promote and maintain granulomatous lesions. During active disease, lymphocytes in the granulomas are predominantly helper T (CD4) lymphocytes. These lesions usually heal with complete preservation of the parenchyma; however, in approximately 20% of the lesions, fibroblasts proliferate at the periphery of the granuloma and may produce fibrotic scar tissue. Macrophages within sarcoidosis granulomas produce

and secrete 1,25-$(OH)_2$ -D_3 , the active form of vitamin D typically produced in the kidneys. Excess vitamin D results in hypercalcemia and hypercalciuria in patients with sarcoidosis.

Clinical Manifestations.

The initial clinical presentation is extremely variable, depending on the organ systems involved, but manifestations in children usually include weight loss, cough, fatigue, bone and joint pain, and anemia. In adults and children, the lung is the most frequently affected organ but the pulmonary involvement is variable in its extent and characteristics. Parenchymal infiltrates, miliary nodules, and hilar and paratracheal lymphadenopathy occur (Fig. 155–1). Pulmonary function tests primarily show restrictive changes. Peripheral lymphadenopathy, eye changes consisting of uveitis or iritis, skin lesions, and hepatic involvement occur frequently. Children younger than 4 yr old may have a distinct form of sarcoidosis consisting of a maculopapular erythematous rash, uveitis, and arthritis but minimal to no pulmonary changes. The arthritis, which can be confused with rheumatoid arthritis, produces large, painless, boggy synovial effusions of the tendon sheaths with little limitation of motion.

Diagnosis.

There are no specific diagnostic tests. An elevated erythrocyte sedimentation rate, hyperproteinemia, hypercalcemia, hypercalciuria, eosinophilia, and an elevated angiotensin-converting enzyme level are common. The **Kveim test,** consisting

Figure 155-1 Sarcoidosis in a white 10-yr-old girl. There are widely disseminated peribronchial infiltrations, multiple small nodular densities, hyperaeration of the lungs, and hilar lymphadenopathy.

of intradermal injection of material from a sarcoid lesion and observation for the formation of a granuloma several weeks later, is used infrequently because of the difficulty in obtaining standardized test material and reports of varying sensitivity and specificity of the test. Definitive diagnosis requires demonstration of the characteristic noncaseating granulomatous lesions in a biopsy of tissue from an affected area. Significant eye disease and renal damage from hypercalciuria can occur without symptoms; therefore, all patients with sarcoidosis should be evaluated at the initial presentation and monitored at regular intervals for evidence of ocular disease and hypercalciuria.

Because of its protean manifestations, the differential diagnosis of sarcoidosis is extremely broad and includes tuberculosis, pulmonary mycoses (histoplasmosis, blastomycosis, and coccidioidomycosis), lymphoma, Crohn disease, and inflammatory ocular lesions such as phlyctenular conjunctivitis.

Treatment.

Treatment is symptomatic and supportive. The decision to treat with potentially harmful agents is often difficult because the prognosis and natural history of sarcoidosis in children are uncertain. Spontaneous recovery may occur after a prolonged illness of several months to several years, or the condition may be chronic, with progressive lung disease. Corticosteroids may suppress the acute manifestations, especially the inflammatory ocular lesions, progressive pulmonary disease, and hypercalcemia/hypercalciuria. Methotrexate may be considered in severe cases that are unresponsive to corticosteroid therapy. Eye involvement may lead to blindness; therefore, therapy with topical corticosteroids with careful monitoring is warranted.

Pulmonary function tests are useful in following the progress of lung involvement. Angiotensin-converting enzyme levels have been shown to correlate with disease activity.

Chapter 156 - Kawasaki Disease

Anne H. Rowley
Stanford T. Shulman

Kawasaki disease, formerly known as mucocutaneous lymph node syndrome or infantile polyarteritis nodosa, is an acute febrile vasculitis of childhood first described by Dr. Tomisaku Kawasaki in Japan in 1967. The disorder occurs worldwide, with Asians at highest risk. Approximately 20% of untreated patients develop coronary artery abnormalities including aneurysms, with the potential for the development of coronary artery thrombosis or stenosis, myocardial infarction, aneurysm rupture, and sudden death. Kawasaki disease has replaced acute rheumatic fever as the leading cause of acquired heart disease in children in the United States and Japan.

Etiology.

The cause of the illness remains unknown, but clinical and epidemiologic features strongly support an infectious origin. These features include the age group affected, the occurrence of periodic epidemics with a wavelike geographic spread of illness during the epidemic, the self-limited nature of the illness, and the clinical features of fever, rash, enanthem, conjunctival injection, and cervical lymphadenopathy. One hypothesis is that a ubiquitous agent causes Kawasaki disease and that

symptomatic illness occurs only in genetically predisposed hosts. The infrequent occurrence of the illness in infants younger than 4 mo may be due to passive maternal antibody, and the virtual absence of cases in adults may be due to widespread immunity.

Epidemiology.

It is estimated that at least 3,000 cases are diagnosed annually in the United States. The incidence of Kawasaki disease in Asian children is substantially higher than in other racial groups, but the illness occurs worldwide in all ethnic groups. In Japan, more than 170,000 cases have been reported since the 1960s. Kawasaki disease is not a new illness; autopsy reports of infantile periarteritis nodosa before the 1960s appear in retrospect to have represented fatal Kawasaki disease. The disorder bears marked similarities to measles infection and may have been particularly difficult to identify before the development of measles vaccine. The illness occurs predominantly in young children; 80% of patients are younger than 5 yr, and only occasionally are teenagers and adults affected.

Pathogenesis.

Kawasaki disease causes a severe vasculitis of all blood vessels but predominantly affecting the medium-sized arteries, with predilection for the coronary arteries. Pathologic examination of fatal cases in the acute or subacute stages reveals edema of endothelial and smooth muscle cells with intense inflammatory infiltration of the vascular wall, initially by polymorphonuclear cells but rapidly changing to macrophages, lymphocytes (which are mostly CD8 T cells), and plasma cells. IgA plasma cells are prominent in the inflammatory infiltrate. In the most severely affected vessels, inflammation involves all three layers of the vascular wall, with destruction of the internal elastic lamina. The vessel loses its structural integrity and weakens, resulting in dilatation or aneurysm formation. Thrombi may form in the lumen and obstruct blood flow. In the healing phase, the lesion becomes progressively fibrotic, with marked intimal proliferation, which may result in stenotic occlusion of the vessel over time.

An inflammatory infiltrate, including IgA plasma cells, is present in selected nonvascular tissues in acute Kawasaki disease, including myocardium, upper respiratory tract, pancreas, kidney, and biliary tract, suggesting that the infectious agent may cause a host immune response in a variety of nonvascular tissues. No significant sequelae appear to occur in any of these nonvascular tissues following the illness.

In the subacute phase of illness, elevated levels of all the serum immunoglobulins are present, suggesting that a vigorous antibody response occurs. It is unclear whether the etiologic agent, the host immune response, or both are the major factors leading to coronary disease.

Clinical Manifestations.

Fever is generally high spiking (to 104°F or higher), remittent, and unresponsive to antibiotics. The duration of fever is generally 1–2 wk without treatment but may persist for 3–4 wk. Prolonged fever has been shown to be a risk factor for the development of coronary artery disease. The other characteristic features of the illness are bilateral bulbar conjunctival injection, usually without exudate; erythema of the oral and pharyngeal mucosa with “strawberry” tongue and dry, cracked lips; erythema and swelling of the hands and feet; rash of various forms (maculopapular, erythema multiforme, or scarlatiniform) with accentuation in the groin area; and nonsuppurative cervical lymphadenopathy, usually unilateral, with a node size of 1.5?cm or greater in diameter. Perineal desquamation is common in the acute phase. Periungual desquamation of the fingers and toes begins 1–3 wk after the onset of illness and may progress to involve the entire hand and foot.

Other features include extreme irritability, especially in infants, aseptic meningitis, diarrhea, mild hepatitis, hydrops of the gallbladder, urethritis and meatitis with sterile

pyuria, otitis media, and arthritis. Arthritis is more common in girls and may occur early in the illness with fever and other acute manifestations or may develop during the 2nd–3rd week, generally affecting hands, knees, ankles, or hips.

Cardiac involvement is the most important manifestation of Kawasaki disease. Myocarditis manifested by tachycardia and decreased ventricular function occurs in at least 50% of patients. Pericarditis with a small pericardial effusion is common during the acute illness. Coronary artery aneurysms generally develop in up to 25% of untreated patients during the 2nd–3rd wk of illness and can be detected by two-dimensional echocardiography. Valvular regurgitation and systemic artery aneurysms may occur but are uncommon. Giant coronary artery aneurysms (=8?mm internal diameter) pose the greatest risk for rupture, thrombosis or stenosis, and myocardial infarction.

Kawasaki disease is generally divided into three clinical phases. The **acute febrile phase**, which usually lasts 1–2 wk, is characterized by fever and the other acute signs of illness. The **subacute phase** begins when fever and other acute signs have abated, but irritability, anorexia, and conjunctival injection may persist. The subacute phase is associated with desquamation, thrombocytosis, the development of coronary aneurysms, and the highest risk of sudden death. This phase generally lasts until about the 4th wk. The **convalescent phase** begins when all clinical signs of illness have disappeared and continues until the erythrocyte sedimentation rate (ESR) returns to normal, approximately 6–8 wk after the onset of illness.

Certain clinical and laboratory findings may predict a more severe outcome. These include male gender, age younger than 1 yr, prolonged fever, recurrent fever after an afebrile period, and the following laboratory values at presentation: low hemoglobin or platelet levels, high neutrophil and band counts, and low albumin and age-adjusted serum IgG levels. However, scoring systems based on these factors have not proven sensitive enough to allow for selective treatment of patients based on risk.

Diagnosis.

The diagnosis of Kawasaki disease is based on demonstration of characteristic clinical signs (Box 156–1). The diagnostic criteria require the presence of fever for at least 5 days and at least four of five of the other characteristic clinical features of illness. Atypical or incomplete cases in which a patient has fever with fewer than four other features of the illness and then develops coronary artery disease have been described worldwide. Incomplete cases are most frequent in infants, who unfortunately have the highest likelihood of developing coronary artery disease.

Recognition depends on a high index of suspicion and knowledge of the characteristic clinical features of the illness. Unfortunately, if the diagnosis is not made and treatment not instituted, a patient may suffer sudden death secondary to myocardial infarction or coronary aneurysm rupture, or may

Box 156-1. Diagnostic Criteria for Kawasaki Disease

Fever lasting for at least 5 days*

Presence of at least four of the following five signs:

1. Bilateral bulbar conjunctival injection, generally nonpurulent
2. Changes in the mucosa of the oropharynx, including injected pharynx, injected and/or dry fissured lips, strawberry tongue
3. Changes of the peripheral extremities, such as edema and/or erythema of the hands or feet in the acute phase; or periungual desquamation in the subacute phase
4. Rash, primarily truncal; polymorphous but nonvesicular
5. Cervical adenopathy, =1.5?cm, usually unilateral lymphadenopathy

Illness not explained by other known disease process

*Experienced physicians may make the diagnosis of Kawasaki disease (and institute treatment) before the 5th day of fever in patients with classic features of the illness.

develop serious asymptomatic coronary disease that is not diagnosed until symptoms develop in young adulthood.

DIFFERENTIAL DIAGNOSIS.

The differential diagnosis of Kawasaki disease includes scarlet fever, toxic shock syndrome, measles, drug hypersensitivity reactions including Stevens-Johnson syndrome, juvenile rheumatoid arthritis, and, more rarely, Rocky Mountain spotted fever and leptospirosis. Some features of uncomplicated measles that help to distinguish it from Kawasaki disease include the presence of exudative conjunctivitis, Koplik spots, rash that begins on the face behind the ears, and a low white blood cell count and ESR. Some features of drug reactions, such as the presence of periorbital

edema, oral ulcers, and a low ESR, may help to distinguish these reactions from Kawasaki disease. Toxic shock syndrome may be distinguished by the presence of hypotension, renal involvement, elevated creatine phosphokinase level, and a focus of *Staphylococcus aureus* infection. A common clinical problem is the differentiation of scarlet fever from Kawasaki disease in a child who is a group A streptococcal carrier. Because patients with scarlet fever have a rapid clinical response to penicillin therapy, such treatment for 24–48?hr with clinical reassessment at that time generally clarifies the diagnosis. The presence of lymphadenopathy, hepatosplenomegaly, and an evanescent, salmon-colored rash suggests a diagnosis of juvenile rheumatoid arthritis. Accurate diagnosis of incomplete cases remains a significant challenge for clinicians. Unusual cases should be referred to a center with experience in the diagnosis of Kawasaki disease.

Laboratory Findings.

No specific diagnostic test for Kawasaki disease exists, but certain laboratory findings are characteristic. The white blood cell count is normal to elevated, with a predominance of neutrophils and immature forms. Elevated ESR, C-reactive protein, and other acute phase reactants are almost universally present in the acute phase of illness and may persist for 4–6 wk. Normocytic anemia is common. The platelet count is generally normal in the 1st wk of illness and rapidly increases by the 2nd–3rd wk of illness, sometimes exceeding 1,000,000/mm^3 . Antinuclear antibody and rheumatoid factor are not detectable. Sterile pyuria, mild elevations of the hepatic transaminases, and cerebrospinal fluid pleocytosis may be present.

Two-dimensional echocardiography is the most useful test to monitor the potential development of coronary artery abnormalities and should be performed by a pediatric cardiologist. The test should be performed at diagnosis and again after 2–3 wk of illness. If results of both of these are normal, a repeat study is performed 6–8 wk after onset of illness. If coronary abnormalities are not detected by echocardiography by 6–8 wk after onset of illness, when the ESR has normalized, additional follow-up studies are optional. Some centers routinely perform echocardiography again 1 yr after onset of illness. However, Kawasaki disease is an acute vasculitis; there is no convincing evidence of long-term cardiovascular sequelae in children who do not develop coronary abnormalities within 2 mo after the onset of illness.

For patients who develop coronary artery abnormalities, more frequent echocardiographic studies and potentially angiography may be indicated. Treatment of such patients should be determined in consultation with a pediatric cardiologist.

Treatment.

Patients with acute Kawasaki disease should be treated with intravenous immunoglobulin (IVIG) and high-dose aspirin as soon as possible after diagnosis (Box 156–2). The mechanism of action of IVIG in Kawasaki disease is unknown, but treatment results in rapid defervescence and resolution of clinical signs of illness in most patients. IVIG reduces the prevalence of coronary disease from 20–25% in children treated with aspirin alone to 2–4% in those treated with IVIG and aspirin

Box 156-2. Treatment of Kawasaki Disease

ACUTE STAGE

Intravenous immunoglobulin 2?g/kg over 10–12?hr *with* aspirin 80–100?mg/kg/24?hr divided every 6?hr orally until 14th illness day

CONVALESCENT STAGE

Aspirin 3–5?mg/kg once daily orally until 6–8 wk after illness onset

LONG-TERM THERAPY FOR THOSE WITH CORONARY ABNORMALITIES

Aspirin 3–5?mg/kg once daily orally ± dipyridamole 4–6?mg/kg/24?hr divided in two or three doses orally (most experts add warfarin for those patients at particularly high risk of thrombosis)

ACUTE CORONARY THROMBOSIS

Prompt fibrinolytic therapy with tissue plasminogen activator, streptokinase, or urokinase under supervision of a pediatric cardiologist

within the first 10 days of illness. In addition, consideration should be given to treatment of patients diagnosed after the 10th illness day if fever has persisted, because the anti-inflammatory effect may be helpful, although the effect of such therapy on the risk of developing coronary aneurysms is unknown. Aspirin is decreased from anti-inflammatory to antithrombotic doses (3–5?mg/kg/24?hr as a single dose) on the 14th illness day or when a patient has been afebrile for at least 3–4 days. Aspirin is continued for its antithrombotic effect until 6–8 wk after onset, when the ESR has normalized, in patients who have not developed abnormalities detected by echocardiography.

Occasional patients do not respond to an initial IVIG infusion or have only a partial response. Strong consideration should be given to re-treatment of these patients with an additional infusion of IVIG, 2?g/kg. The use of corticosteroids in Kawasaki disease remains controversial; if administered, such therapy generally should be reserved for patients with persistent fever following two 2?g/kg infusions of IVIG.

Patients with a small solitary aneurysm should continue aspirin indefinitely. Patients with larger or numerous aneurysms may require the addition of dipyridamole or warfarin therapy; such decisions should be made in consultation with a pediatric cardiologist. Acute thrombosis may occasionally occur in an aneurysmal coronary artery. Thrombolytic therapy may be lifesaving in this circumstance. Abciximab has been used in some patients with Kawasaki disease who develop giant coronary aneurysms or possible thrombosis. Little data regarding efficacy are available, but the drug may reduce thrombotic complications. Long-term follow-up of patients with aneurysms should include echocardiography, stress testing, and possibly angiography. Catheter intervention with percutaneous transluminal coronary rotational ablation, directional coronary atherectomy, and stent implantation are promising therapeutic strategies for the management of coronary stenosis caused by Kawasaki disease.

Patients receiving long-term aspirin therapy are candidates for influenza vaccine to reduce the risk of Reye syndrome. The risk of Reye syndrome in children who take salicylates and who receive varicella vaccine is believed to be much lower than with wild-type varicella. Physicians must weigh the relative risk of vaccine in children on long-term aspirin therapy against the risk of natural varicella infection. Patients treated with 2?g/kg IVIG should have measles-mumps-rubella and varicella vaccines delayed for 11 mo because the presence of specific antiviral antibody in IVIG may interfere with the immune response to parenteral live-virus vaccines.

Complications and Prognosis.

Recovery is complete and without apparent long-term effects for patients who do not develop coronary disease. Recurrent illness occurs in only 1–3% of cases.

The prognosis for patients with coronary abnormalities depends on the severity of coronary disease. In Japan, fatality rates are now less than 0.1%. Overall, 50% of coronary artery aneurysms resolve echocardiographically by 1–2 yr after the illness. However, intravascular ultrasonography has demonstrated that resolved aneurysms are associated with marked intimal thickening and abnormal functional behavior of the vessel. Giant aneurysms are unlikely to resolve and are most likely to lead to thrombosis or stenosis. Coronary artery bypass grafting may be required if myocardial perfusion is significantly impaired, and it is best accomplished with the use of arterial grafts, which grow with the child and are more likely to remain patent than venous grafts. Heart transplantation has been required in rare cases in which revascularization is not feasible because of distal coronary stenosis or aneurysms or severe myocardial dysfunction. Whether the presence of coronary artery abnormalities resulting from Kawasaki disease predisposes to the development of atherosclerotic heart disease in young adulthood is unknown.

Chapter 157 - Vasculitis Syndromes

Michael L. Miller
Lauren M. Pachman

Vasculitis in childhood is a result of a spectrum of causes ranging from idiopathic conditions with primary vessel inflammation to syndromes following exposure to known antigens (e.g., infectious agents, drugs causing hypersensitivity reactions). Vasculitis is also a component of many autoimmune diseases. The extent of vessel damage can range from moderate, as in most children with Henoch-Schönlein purpura (HSP), to severe, as in children with polyarteritis nodosa. Most classifications of the vasculitic syndromes are based on the size and location of the blood vessels that are primarily involved, as well as the type of inflammatory infiltrate. The affected target vessels range in size from large afferent vessels, in Takayasu arteritis (TA), to capillary and arteriolar occlusion, characteristic of juvenile dermatomyositis. The inflammatory infiltrate can include various amounts of polymorphonuclear, mononuclear, and eosinophilic cells.

Immune complexes play a key role in the pathophysiology of many vasculitic syndromes. Immune complexes activate complement, releasing chemotactic fragments (C3a, C5a) that attract inflammatory cells. It is speculated in many vasculitic syndromes that immune complexes, after binding to endothelial cells, increase synthesis of adhesion molecules on the cell surfaces. These adhesion molecules bind to other adhesion molecules on circulating polymorphonuclear leukocytes attracted to the vicinity by chemotactic molecules. Subsequent lysosomal release of digestive enzymes from these leukocytes in many vasculitic syndromes destroys the cellular matrix of the blood vessels and surrounding tissues. In the process of degranulation, the polymorphonuclear leukocytes may disintegrate to the “nuclear dust” typical of leukocytoclastic angiitis (Fig. 157–1).

The signs and symptoms of the vasculitic syndromes are nonspecific and tend to overlap, but certain clinical features are useful in distinguishing the type of vasculature that is primarily affected. Palpable purpura suggests small vessel vasculitis located deep in the papillary dermis, whereas a circumscribed tender nodule is more likely a result of involvement of medium-sized vessels.

157.1 Henoch-Schönlein Purpura

HSP, also known as anaphylactoid purpura, is a vasculitis of small vessels. It is the most common cause of nonthrombocytopenic purpura in children.

Epidemiology.

The etiology of HSP is unknown, but HSP typically follows an upper respiratory tract infection. The incidence and prevalence of HSP are probably underestimated because cases are not reported to public health agencies. However, of 31,333 new patients seen at 54 pediatric rheumatology centers in the United States, 1,120 had some form of vasculitis and 558 were classified as HSP. Although HSP accounted for 1% of hospital admissions in the past, changes in medical practice have reduced the frequency of admissions; 0.06% of admissions (62/9,083 in 1997) were for HSP at one large Midwestern pediatric center. This illness is more frequent in children than adults, with most cases occurring between 2–8 yr of age, most frequently in the winter months. Males are affected twice as frequently as females. The overall incidence is estimated to be 9/100,000 population.

Pathogenesis.

The specific pathogenesis of HSP is not known, although in specific populations, patients with HSP have an significantly higher frequency of HLA-DRB1*07 than geographic controls. Increased serum concentrations of the cytokines tumor necrosis factor-a (TNFa) and interleukin (IL)-6 have been identified in active disease. In one study, almost half of the

Figure 157.1-1 Histopathology of a skin biopsy from a patient with Henoch-Schönlein purpura showing leukocytoclastic vasculitis with nuclear degeneration (“nuclear dust”).

patients had elevated antistreptolysin O (ASO) antibodies, implicating group A *Streptococcus*. This illness is considered by histopathology to be an IgA-mediated vasculitis of small vessels. Immunofluorescence techniques show deposition of IgA and C3 in the small vessels of the skin and the renal glomeruli, but the role of complement activation is controversial.

Clinical Manifestations.

The disease onset may be acute, with the appearance of several manifestations simultaneously, or insidious, with sequential occurrence of symptoms over a period of weeks or months. Low-grade fever and fatigue occur in more than half of affected children. The typical rash and the clinical symptoms of HSP are a consequence of the usual location of the acute small vessel damage primarily in the skin, gastrointestinal tract, and kidneys.

The hallmark of the disease is the rash, beginning as pinkish maculopapules that initially blanch on pressure and progress to petechiae or purpura, which are characterized clinically as palpable purpura that evolve from red to purple to rusty brown before they eventually fade (Fig. 157–2). The lesions tend to occur in crops,

last from 3–10 days, and may appear at intervals that vary from a few days to as long as 3–4 mo. In fewer than 10% of children, recurrence of the rash may not end until as late as a year, and rarely several years, after the initial episode. Damage to cutaneous vessels also results in local angioedema, which may precede the palpable purpura. Edema occurs primarily in dependent areas—for example, below the waist, over the buttocks (or on the back and posterior scalp in the infant), or in areas of greater tissue distensibility, such as the eyelids, lips, scrotum, or dorsum of the hands and feet.

Arthritis, present in more than two thirds of children with HSP, is usually localized to the knees and ankles and appears to be concomitant with edema. The effusions are serous, not hemorrhagic, in nature and resolve after a few days without residual deformity or articular damage. They may recur during a subsequent reactive phase of the disease.

Edema and damage to the vasculature of the gastrointestinal tract may also lead to intermittent abdominal pain that is often colicky in nature. More than half of patients have occult heme-positive stools, diarrhea (with or without visible blood), or hematemesis. The recognition of peritoneal exudate, enlarged mesenteric lymph nodes, segmental edema, and hemorrhage into the bowel may prevent unnecessary laparotomy for acute abdominal pain. Intussusception may occur, which is suggested by an empty right lower abdominal quadrant on physical examination or by **currant jelly stools**, which may be followed by complete obstruction or infarction with bowel perforation.

Figure 157.1-2 Henoch-Schönlein purpura. (From Korting GW: *Hautkrankheiten bei Kindern und Jugendlichen*, 3rd ed. Stuttgart, FK SchattauerVerlag, 1982.)

Several other organ systems may be involved during the acute phase of disease. Renal involvement occurs in 25–50% of children, and hepatosplenomegaly and lymphadenopathy may also be present during active disease. A rare but potentially serious outcome of central nervous system (CNS) involvement is the development of seizures, paresis, or coma. Other rare complications include rheumatoid-like nodules, cardiac and eye involvement, mononeuropathies, pancreatitis, and pulmonary or intramuscular hemorrhage.

Diagnosis.

The pattern of crops of palpable purpuric lesions of similar hue in dependent areas of the body is characteristic of HSP. Diagnostic uncertainty arises when the symptom complex of edema, rash, arthritis with abdominal complaints, and renal findings occurs for a prolonged period. HSP can occur with other forms of vasculitis or autoimmune disease such as familial Mediterranean fever or inflammatory bowel disease. In polyarteritis nodosa, the cutaneous lesions are different, and peripheral neurologic and cardiac manifestations are more common. Palpable purpura can occur in meningococcemia, if there are pre-existing coagulation abnormalities such as factor V Leiden, protein S, or protein C deficiency. The presentation of unremitting fever, a maculopapular rash that does not reappear in crops but is prominent on the lower extremities, and peripheral arthritis suggests Kawasaki disease. HSP must be distinguished from systemic-onset juvenile rheumatoid arthritis, in which the salmon-pink rash is evanescent and maculopapular, with swelling that does not extend beyond the joint.

Laboratory Findings.

Routine laboratory tests are neither specific nor diagnostic. Affected children often have a moderate thrombocytosis and leukocytosis. The erythrocyte sedimentation rate (ESR) may be elevated. Anemia may result from chronic or acute gastrointestinal blood loss. Immune complexes are often present, and 50% of patients have elevated concentrations of IgA as well as IgM but are usually negative for antinuclear antibodies (ANAs), antibodies to nuclear cytoplasmic antigens (ANCAs), and rheumatoid factor (even in the presence of rheumatoid nodules). Anticardiolipin or antiphospholipid antibodies may be present and contribute to the intravascular coagulopathy. Intussusception is usually ileoileal in location; barium enema may be used for both identification and nonsurgical reduction. Renal involvement is manifested by red blood cells, white blood cells, casts, or albumin in the urine.

Definitive diagnosis of vasculitis, confirmed by biopsy of an involved cutaneous site, shows leukocytoclastic angiitis. Renal biopsy may show IgA mesangial deposition and occasionally IgM, C3, and fibrin. Patients with IgA nephropathy may have elevated plasma antibody titers against *H. parainfluenzae*.

Treatment.

Symptomatic treatment, including adequate hydration, bland diet, and pain control with acetaminophen, is provided for self-limited complaints of arthritis, edema, fever, and malaise. Avoidance of competitive activities and of maintaining the lower extremities in persistent dependence may decrease local edema. If edema involves the scrotum, elevation of the scrotum and local cooling, as tolerated, may decrease discomfort.

Intestinal complications (e.g., hemorrhage, obstruction, and intussusception) may be life threatening and managed with corticosteroids and, when necessary, reduction (by air or barium) or resection of the intussusception. Therapy with oral or intravenous corticosteroids (1–2?mg/kg/24?hr) is often associated with dramatic improvement of both gastrointestinal and CNS complications, which may recur for as long as 3 yr.

Management of renal involvement is the same as for other forms of acute glomerulonephritis (see Chapter 504). If anticardiolipin or antiphospholipid antibodies are identified and thrombotic events have occurred, aspirin (81?mg; a “baby” aspirin) given once may decrease the risks associated with a

hypercoagulable state. Rheumatoid nodules may respond to alternate-day colchicine (0.6?mg/24?hr every other day).

Complications.

The major complications of HSP are renal involvement, including nephrotic syndrome, and bowel perforation. An infrequent complication of scrotal edema is testicular torsion, which is quite painful and must be treated promptly.

Prognosis.

HSP is a self-limited vasculitic disease with an excellent overall prognosis. Chronic renal disease may result in morbidity: a population-based study indicated that fewer than 1% of patients with HSP develop persistent renal disease and fewer than 0.1% develop serious renal disease. Rarely, death may occur during the acute phase of the disease as a result of bowel infarction, CNS involvement, or renal disease. Occasionally, children who present with an HSP-like syndrome acquire characteristics of other connective tissue diseases.

157.2 Takayasu Arteritis

TA, also known as pulseless disease, is a chronic vasculitis of large vessels.

Epidemiology.

TA is infrequently reported in children in the United States but is more common in Asian and Indian populations. Children of all ethnic backgrounds have been affected. After HSP and Kawasaki disease, TA may be the third most common form of childhood vasculitis in the world. There is a 2.5:1 female:male ratio. About one third of cases have onset before age 20 yr, and symptoms usually appear after age 10 yr, although children as young as 8 mo have been affected. The interval from initial presentation to diagnosis in children has been reported to be as long as 19 mo, almost four times the interval reported for adults.

Pathogenesis.

TA is a chronic inflammatory and obliterative disease of large vessels, with preference for the aorta and its major branches. Renal lesions include mesangial proliferative, membranoproliferative, and crescentic glomerulonephritis as well as amyloidosis.

Although the antigen responsible for inciting TA has yet to be defined, exposure to tuberculosis has been reported to be associated with the disease in some studies in Asia. Identification of critical amino acid residues of the HLA-B molecule at position 63(Glu) and 67(Ser) suggests a specific antigen-binding site in some cases. Study of non-Asian populations has provided evidence of similarities of sequence. Immune complex formation and complement activation have been frequently identified as well as anti-endothelial antibodies, which up-regulate the expression of endothelial adhesion molecules, but it is uncertain why only large vessels are affected. Cytokines, including IL-6, are increased, and there is a restricted usage of T cell receptors (V and V*), which suggests there is an immune response to an antigen.

Clinical Manifestations.

Early disease manifestations, during the prepulseless phase, include night sweats, anorexia, weight loss, fatigue, myalgia, and arthritis, often followed by unexplained hypertension. During the pulseless phase, systemic symptoms are twice as frequent in children compared with adults; splenomegaly may be found. Dermatologic features include erythema nodosum, a malar rash, and erythema induratum. Cardiac involvement includes dilated cardiomyopathy, myocarditis, and pericarditis. Other associated conditions include interstitial lung disease, pneumonic consolidation,

ulcerative colitis, rheumatoid arthritis, and polymyositis.

Diagnosis.

During the pulseless phase, a characteristic bruit, often over the carotid or subclavian arteries, may be present on auscultation. Children may have diminished or absent radial pulses; limb claudication appears less frequently than in adults. If these symptoms occur in the 1st yr of life, arterial damage may be accompanied by papular rash, uveitis, symmetric polyarthritis, and granulomatous lesions typical of sarcoid, a condition sometimes termed **juvenile systemic granulomatosis.**

Prompt diagnosis with institution of therapy is essential and may prevent progression of vascular lesions. The presence of intermittent unexplained systemic symptoms of variable duration in conjunction with an elevated ESR should prompt periodic auscultation of large arteries and blood pressure measurements in all four limbs.

This illness must be differentiated from acute rheumatic fever or juvenile arthritis. Because aortitis and aortic regurgitation may develop in TA, other disorders with these findings must also be considered, including Behçet disease, Cogan syndrome (a syndrome of ocular inflammation, vestibuloauditory abnormalities, and systemic vasculitis), relapsing polychondritis, ankylosing spondylitis (enthesitis-related arthritis), and seropositive rheumatoid arthritis. **Juvenile temporal arteritis** is rare, may be associated with a normal ESR, and is not associated with systemic symptoms.

Laboratory Findings.

The ESR is significantly elevated, typically 60?mm/hr or greater (Westergren), and a microcytic hypochromic anemia with a leukocytosis is usual. A polyclonal hypergammaglobulinemia is present in one third of cases. Circulating immune complexes may remain elevated when the ESR has normalized, reflecting continued disease activity.

The diagnosis can be confirmed by angiography, which often outlines a massively dilated aortic arch, with aneurysmal dilatation and stenosis of various large vessels—carotids, subclavian, abdominal aorta, or rarely in children, lesions of the coronary artery (Fig. 157–3). Magnetic resonance angiography may be

Figure 157.2-3 Angiogram of a child with Takayasu arteritis showing massive bilateral carotid dilatation, stenosis, and poststenotic dilatation.

helpful as a noninvasive test for subsequent monitoring of affected vessels.

Treatment.

Early identification and surgical excision of the predominant lesions are essential, in conjunction with institution of appropriate immunosuppressive therapy. Prednisone (orally or intravenously) is administered in conjunction with other agents. Methotrexate has been useful in some situations, but cyclophosphamide (orally or intravenously) may often be needed to control the intense inflammatory response. Cyclophosphamide increases the risk of *Pneumocystis carinii* and therefore prophylactic trimethoprim-sulfamethoxazole is recommended. More than 50% of cases achieve remission after the 1st course of therapy, but about one fourth of cases never achieve remission. The 5-yr mortality has been reported to be as high as 35%. Supportive care includes management of hypertension and psychologic support. There is no indication for genetic counseling.

Complications.

The most dreaded complication of this often fatal illness is an aneurysmal rupture. Therefore, the dilated area is often excised and replaced with an ileal vascular graft. Prevention of chronic hypertension and decreased perfusion can sometimes be accomplished by excision of a stenotic area with graft replacement or by insertion of an intraluminal stent to forestall the redevelopment of stenosis.

Prognosis.

In the past, the mortality rate has been high. The outlook for these children remains guarded. The best outcome appears to follow early diagnosis and institution of medical and surgical therapy.

157.3 Polyarteritis Nodosa

Polyarteritis nodosa (PAN) is a necrotizing vasculitis affecting small- and medium-sized arteries. Aneurysms and nodules may form at irregular intervals throughout affected arteries.

Epidemiology.

PAN occurs rarely during childhood. Boys and girls appear to be equally affected, with a peak at 10 yr of age. The cause is unknown, although the occurrence of PAN after upper respiratory tract infections, group A *Streptococcus* infection, and chronic hepatitis B infection suggests that PAN represents a postinfectious autoimmune response to these agents in susceptible individuals. Other infections, including infectious mononucleosis, tuberculosis, cytomegalovirus, and parvovirus, have also been associated with PAN.

Pathogenesis.

Biopsy reveals a necrotizing vasculitis with lymphocytic infiltration affecting all layers of small- and medium-sized muscular arteries (Fig. 157–4). Involvement is usually segmental, including bifurcations of vessels. Different stages of inflammation are found, ranging from mild inflammation to extensive fibrinoid necrosis associated with thrombosis and infarction. Aneurysm formation is common. Vascular occlusion may also occur as a result of postinflammatory fibrosis. Renal arterial involvement is found in the majority of patients; glomerular involvement is variable.

Clinical Manifestations.

The clinical presentation is variable but generally reflects the location of vessels that have become inflamed. Children may present with fever of unknown origin before other findings develop. Weight loss and severe abdominal pain suggest mesenteric arterial inflammation and possible thrombosis. Renovascular arteritis can result in hypertension, hematuria, or proteinuria. Vasculitis affecting the skin may be manifested by purpura, edema, and linear erythema with palpable, painful nodules along the course of affected arteries. In cutaneous PAN, the findings are limited to the skin. Arteritis affecting the nervous system may result in cerebrovascular accidents, transient ischemic attacks, psychosis, and ischemic

Figure 157.3-4 Biopsy of a medium-sized muscular artery that exhibits marked fibrinoid necrosis of the vessel wall (*arrow*). (From Cassidy JT, Petty RE: Juvenile rheumatoid arthritis. In *Textbook of Pediatric Rheumatology*, 3rd ed. Philadelphia, WB Saunders, 1995.)

peripheral neuropathy, with peripheral paresthesias or weakness. Cardiac involvement characterized by myocarditis may result in myocardial ischemia and heart failure; pericarditis and arrhythmias have also been reported. Less common findings include testicular pain that simulates testicular torsion, bone pain, and retinal arteritis, which may cause blindness. Arthralgia, arthritis, or myalgias may be encountered.

Diagnosis.

Diagnosis of PAN requires demonstration of findings characteristic of vasculitis on biopsy or angiography. Biopsy of suggestive cutaneous lesions may reveal vasculitis (see Fig. 157–4). Renal biopsy in patients with renal manifestations may show characteristic necrotizing arteritis. Electromyography in children with peripheral neuropathy may identify affected sites; sural nerve biopsy may show an associated diagnostic vasculitis. Angiography demonstrates areas of aneurysmal dilatation, at branch points of arteries, or segmental stenosis (Fig. 157–5). The renal and mesenteric arteries are often involved. Evidence for previous or active infection should be sought in children with suspected PAN.

DIFFERENTIAL DIAGNOSIS.

Early skin lesions may resemble those of HSP; the finding of nodular lesions and systemic findings distinguish PAN. Pulmonary lesions suggest Wegener granulomatosis (WG) or Goodpasture syndrome. Eosinophilia is noted in Churg-Strauss syndrome and eosinophilic fasciitis. Other rheumatic diseases, including systemic lupus erythematosus, dermatomyositis, and scleroderma, have characteristic target organ involvement distinct from PAN. Prolonged fever and weight loss can also characterize inflammatory bowel disease or malignancies.

Laboratory Findings.

An elevated ESR is often the earliest finding. Anemia and leukocytosis are usually present eventually. Hypergammaglobulinemia reflects polyclonal B-cell activation. Abnormal urine sediment, proteinuria, and hematuria indicate renal disease. Markers of vasculitis may be useful in monitoring response to therapy. Von Willebrand factor antigen, a molecule found in vascular subendothelium, is released in increased amounts from inflamed vessels. Neopterin is released from macrophages that are activated in some patients with vasculitis. Levels of immune complexes, measured by the Raji cell and C1q assay, may also be elevated. Elevated hepatic enzymes suggest hepatitis B infection, which is more common in adults than in children.

Figure 157.3-5 Celiac angiography of an 18-yr-old boy showing aneurysms in multiple vessels. (From Cassidy JT, Petty RE: Juvenile rheumatoid arthritis. In *Textbook of Pediatric Rheumatology*, 3rd ed.

Philadelphia, WB Saunders, 1995.)

Treatment.

Oral and intravenous corticosteroids have been used, sometimes in combination with oral or intravenous cyclophosphamide. Iloprost, a prostacyclin analog, may be used for endarteritis that is associated with vascular compromise in the extremities.

Complications.

Cutaneous nodules may ulcerate, posing a risk of infection. Hypertension may develop from renal arterial involvement. Cardiac involvement may lead to decreased cardiac function or coronary arterial disease. Hepatic aneurysmal rupture is a rare complication.

Prognosis.

The course of PAN varies from mild disease with few complications to a severe, overwhelming, multiorgan disease leading to death. However, aggressive immunosuppressive therapy has resulted in clinical remission. When renal involvement is present, the 1-yr survival rate was 73% and the 5-yr survival rate was 60%.

157.4 Wegener Granulomatosis

WG is a vasculitis affecting the upper and lower respiratory tract and kidneys, characterized by necrotizing granulomas.

Epidemiology.

The heterogeneity of clinical presentations suggests that a single causative agent is unlikely. Although most cases occur in adults, children can develop WG, which predominates in whites. The cause is unknown, although proteinase 3 (PR3), normally restricted to neutrophil alpha granules, has been found on the surface of neutrophils of patients with WG. Those ANCAs that bind to PR3 are specific for WG, suggesting an etiologic role for abnormal PR3 expression. Interaction of PR3 with the PiZ variant of a_1 -antitrypsin has been found in some studies to increase the risk of developing WG.

Pathogenesis.

Necrotizing granulomas are found in affected organs, including the nasal and sinus mucosa, skin, and lower respiratory tract. In the lungs, infiltrates, alveolar hemorrhage, and vasculitis may also be found. Renal involvement can vary from focal proliferative glomerulonephritis to necrotic crescentic glomerulonephritis.

Clinical Manifestations.

Children initially often complain of nonspecific constitutional symptoms of fever, malaise, weight loss, myalgia, and arthralgia. Many affected children have seasonal allergies. Later symptoms include cough, congestion, and nasal discharge from chronic sinusitis (often with mucosal ulceration and bone destruction from necrotizing granulomas), and hemoptysis and dyspnea from pulmonary lesions (Fig. 157–6). Ophthalmic involvement includes conjunctival and corneal lesions, uveitis, and an invasive orbital pseudotumor. Cranial and peripheral neuropathies due to intracranial granulomas and peripheral granulomatous lesions have been reported. Hematuria and proteinuria due to glomerulonephritis are often later manifestations. Cutaneous lesions may include palpable purpuric nodules and ulcers.

Diagnosis.

The diagnosis of WG should be suspected in children who have severe sinusitis and who develop radiographic pulmonary findings suggestive of granulomas or renal findings consistent with nephritis. High-resolution CT imaging of the chest may reveal

interstitial densities consistent with vasculitis or pulmonary hemorrhage. The diagnosis is confirmed by the presence of anti-PR3 ANCAs and the finding of necrotizing granulomatous angiitis on pulmonary, sinus, or renal biopsy.

DIFFERENTIAL DIAGNOSIS.

Granulomatous lesions can be found in sarcoidosis, in which antibodies to ANCA are absent. Other granulomatous diseases (e.g., tuberculosis) also lack antibodies to ANCA. **Churg-Strauss syndrome** is a vasculitis that can cause chronic sinus lesions; a history of asthma, circulating eosinophilia, and an eosinophilic cutaneous vasculitis distinguish this syndrome from WG. The lesions in Churg-Strauss syndrome are not usually associated with destructive upper airway disease. Other vasculitic syndromes lack the characteristic granulomas on biopsy of affected organs.

Figure 157.4-6 Chest radiograph of a 14-yr-old girl with Wegener granulomatosis showing widespread infiltrates suggestive of pulmonary hemorrhage. There were considerable day-to-day variability and eventual total resolution of these abnormalities after treatment with prednisone and cyclophosphamide. (From Cassidy JT, Petty RE: Juvenile rheumatoid arthritis. In *Textbook of Pediatric Rheumatology*, 3rd ed. Philadelphia, WB Saunders, 1995.)

Laboratory Findings.

Elevated ESR, leukocytosis, thrombocytosis, and anemia may be found. Antibodies to ANCA directed toward PR3 are specific for WG. These antibodies, usually of IgG class, are found on immunofluorescence to be distributed in a diffuse granular staining throughout the cytoplasm (c-ANCA); staining for myeloperoxidase by ANCA in a perinuclear pattern (p-ANCA) is not specific for WG.

Treatment.

Oral and intravenous corticosteroids and cyclophosphamide have been effective in many patients. Methotrexate has also been used with success.

Complications.

Enlarging granulomas may disrupt local anatomy: Intrasinus lesions can invade the orbit; lesions in the ear can result in unilateral deafness. Respiratory complications include pulmonary hemorrhage and upper airway obstruction due to subglottic stenosis. Infectious complications include sinusitis, either as infection of granulomatous lesions or after obstruction, and pneumonia. Chronic glomerulonephritis may result in end-stage renal disease.

Prognosis.

The course is variable. Mortality has been reduced with the introduction of cyclophosphamide and other immunosuppressive agents.

157.5 Other Vasculitic Syndromes

Leukocytoclastic vasculitis refers to a spectrum of vasculitic syndromes, including HSP, as well as to specific biopsy findings. It is characterized by cutaneous vessel inflammation affecting both small arteries and postcapillary venules. Purpura and occasionally urticaria are found, particularly on the extremities. The diagnostic term leukocytoclastic vasculitis is sometimes used for cases similar to HSP but with atypical distribution and associated symptoms. **Hypersensitivity angiitis** is cutaneous vasculitis following exposure to drugs, such as sulfonamides. Clinical manifestations include fever, myalgia, and arthralgia but rarely visceral involvement. Subsequent development of systemic findings indicating more extensive vasculitis suggests the likelihood of another diagnosis such as PAN. For both leukocytoclastic vasculitis and hypersensitivity angiitis, biopsy of lesions may reveal fibrinoid necrosis of blood vessels, perivascular polymorphonuclear infiltrate, and nuclear debris or dust.

Chapter 158 - Musculoskeletal Pain Syndromes

Michael L. Miller

Children with poorly localized pain involving the extremities and with normal findings on physical examination and unremarkable laboratory findings can be considered to have a musculoskeletal pain syndrome (MSPS). MSPS occasionally develops following trauma in children with underlying rheumatic diseases; careful follow up is necessary to distinguish this complication from slowly evolving disease exacerbation. Clinical manifestations of MSPS overlap other conditions, including reflex sympathetic dystrophy (RSD), erythromelalgia, fibromyalgia, and chronic fatigue syndrome (see Chapter 111). Clinical management of these conditions is remarkably similar.

Clinical Manifestations.

The history is sometimes related almost entirely by a parent who notes the child to have pain at rest. If symptoms have persisted for years, adolescents may also report chronic pain, often with inconsistent details, when compared with the history offered by the parent. Location of pain can vary from regional, affecting a single extremity, to generalized. Patients often complain of pain refractory to nonsteroidal anti-inflammatory drugs and analgesic agents. Physical therapy programs may have been tried without success.

Other symptoms associated with pain syndromes include fatigue, sleep problems, and poor school attendance. In contrast to many children with pain due to rheumatic diseases, children with MSPS tend to be depressed at the prospect of returning to school instead of staying home from school. Excellent academic performance often precedes prolonged school absences; it is possible that symptoms develop when a child is unable to maintain continuing academic demands. Parents may have a history of organic or functional pain, sometimes in the same anatomic region that is symptomatic in the child.

Results of the physical examination are unremarkable, with normal strength and no joint swelling or limitation of motion. However, exquisite tenderness to light touch is often elicited over various parts of the extremities, which may not be reproducible on repeat examination. Cold, clammy, cyanotic distal extremities occasionally suggest autonomic dysfunction, such as in RSD. These findings may improve after a child has exercised.

Fibromyalgia is distinguished by the presence of **trigger points**, which are localized areas of tenderness to palpation. These are not always reproducible. One study found many children with fibromyalgia to have hypermobile joints.

There are no specific laboratory findings of MSPS. Anemia and hypothyroidism should be excluded. Imaging studies, particularly plain radiographs, may be necessary to exclude fractures or other pathology; MRI studies may be necessary to exclude ligamentous injury. The need for additional tests is individualized, depending on specific symptoms and physical findings.

Diagnosis.

The diagnosis of musculoskeletal pain syndromes is one of exclusion if careful, repeated physical examinations and laboratory testing do not reveal an etiology. A history of sleep disturbances and widespread musculoskeletal pain associated with tenderness over trigger points on physical examination suggests fibromyalgia.

DIFFERENTIAL DIAGNOSIS.

Because psychiatric disorders can overlap and present with symptoms of MSPS, psychiatric evaluation should be considered for children with these syndromes. Prolonged school absence suggests school phobia (see Chapter 22). When fatigue is more prominent than pain, chronic fatigue syndrome may be considered (see Chapter 111). Physical and sexual abuse may also be manifested by pain syndromes; adolescent girls may have accompanying dizziness. In Munchausen syndrome by proxy (see Chapter 35.3), reports of pain are emphasized with the intent of obtaining unnecessary, often interventional, evaluation.

Repeated physical examinations over time may reveal eventual development of manifestations suggestive of rheumatic or other diseases. Imaging studies, including plain radiographs, MRI, and technetium-99m bone scan, may identify focal pathology resulting from infection, malignancy, or trauma. Weakness may result from thyroid disease, inflammatory myositis, muscular dystrophies, or neurologic disease. Chest pain may be a manifestation of costochondritis, pericarditis, coronary arterial abnormality, or aortic stenosis. Proximal leg pain, often occurring at night, may occur with osteoid osteoma. Back pain may indicate local pathology, including spondylolisthesis, diskitis, and vertebral microfractures. When children with poorly localized pain develop tender entheses, ankylosing spondyloarthropathy should be considered (see Chapter 146).

Treatment.

Successful outcome requires that any underlying psychiatric disorder be identified and treated. Therapy should be directed toward emotional support for the patient and family, relief of symptoms, and minimizing unnecessary and misleading diagnostic

tests and therapeutic regimens. The approach includes a combination of restoration of a normal sleep pattern, rehabilitation strategies including exercise for fatigue, and optimism. Children have been found to improve when the physician and other health care providers can overcome parental resistance to a vigorous physical therapy program for stretching and joint protection. Increasing physical activity at home to improve the level of physical fitness can also help. Some centers use bedtime doses of antidepressants for MSPS. However, if their use is required for more than several weeks, psychiatric evaluation may be necessary to evaluate for depression. For children with persisting symptoms, a rehabilitation program by a physiatrist or referral to a pain clinic may be indicated.

Complications.

Untreated musculoskeletal pain syndromes can result in impaired physical fitness, decreased socialization leading to isolation, prolonged school absences, and lost opportunities for college or vocational training. When families avoid psychologic evaluation or recommendations, children are at risk for developing or exacerbating depression.

158.1 Reflex Sympathetic Dystrophy

Reflex sympathetic (or neurovascular) dystrophy, a condition of unknown cause, is characterized by diffuse limb pain with color and temperature changes thought to result from autonomic nervous system dysfunction. RSD is often a response to physical or emotional distress. A history of physical activities causing repeated impact on the extremities (e.g., ballet dancing) or severe or prolonged emotional trauma (e.g., divorce of the parents, death of a sibling) may be elicited. Children complain of pain worsened by touch or movement, often with dysesthesia and a sensation of temperature changes and swelling. They tend to maintain the hand or foot in a rigid, unusual position, refusing to allow passive motion. Prolonged disuse of the extremity can cause osteopenia; imaging studies (e.g., Doppler flow studies, technetium-99m bone scan) may show either increased or decreased blood flow. Assurance, physical therapy, and, when indicated, counseling can result in resolution of symptoms and physical findings. Relaxation techniques provided by a psychologist may also be useful. When these measures are unsuccessful, sympathetic blocks may be considered.

158.2 Erythromelalgia

Children with erythromelalgia experience episodes of intense pain, erythema, and heat in the distal portion of their legs (rarely, the hands). Mild heat exposure may trigger symptoms that can last for hours and occasionally for days. Although most cases are sporadic, an autosomal dominant hereditary form has been reported. Erythromelalgia can also be associated with peripheral neuropathy, frostbite, hypertension, and rheumatic disease. Treatment includes avoidance of heat exposure and application of cold during attacks. Propranolol, carbamazepine, or sodium nitroprusside may be effective for some affected children.

Chapter 159 - Miscellaneous Conditions Associated with Arthritis

Michael L. Miller

Inflammation of joints or connective tissue may be a manifestation of nonrheumatic conditions. These conditions need to be considered in children with joint complaints whose history, clinical findings, or clinical course are not consistent with rheumatic diseases.

Relapsing Polychondritis.

Relapsing polychondritis is characterized by episodic necrotizing inflammation of cartilage in the outer ear, trachea, and nose. Patients may also develop polyarticular arthritis, ocular inflammation, and hearing loss resulting from inflammation near the auditory and vestibular nerves. Children may initially relate only episodes of intense

Box 159-1. Diagnostic Criteria for Relapsing Polychondritis

Nonerosive seronegative inflammatory polyarthritis

At least three of the following:

- Bilateral auricular chondritis
- Nonerosive seronegative inflammatory polyarthritis
- Nasal chondritis
- Ocular inflammation
- Respiratory tract chondritis
- Audiovestibular chondritis

From McAdam LP, O'Hanlan MA, Bluestone R, et al: Relapsing polychondritis: Prospective study of 23 patients and a review of the literature. Medicine (Baltimore) 1976;55:193–215.

erythema over the outer ears. Later, inflammation may be so severe that it causes loss of cartilage from the outer ear, nose, or trachea. Diagnostic criteria established for adults are useful guidelines for evaluating children who develop suggestive symptoms (Box 159–1). The differential diagnosis includes Cogan syndrome (characterized by auditory nerve inflammation and keratitis but not chondritis) and Wegener granulomatosis (see Chapter 157.4). The clinical course is variable; although some patients respond to corticosteroids, others experience a relentless, progressive course, culminating in death due to airway obstruction.

Mucha-Habermann Disease.

Mucha-Habermann disease, or pityriasis lichenoides et varioliformis acuta (PLEVA), is characterized by recurrent arthritis associated with episodes of vesicular cutaneous lesions, fever, and elevated erythrocyte sedimentation rate. The diagnosis is confirmed by biopsy of skin lesions, which reveals a lymphocytic vasculitis affecting capillaries and venules in the upper dermis.

Sweet Syndrome.

Sweet syndrome, or acute febrile neutrophilic dermatosis, occurs most often in

young women and is rare in children. It is characterized by recurrent fever and raised, tender erythematous plaques over the face, extremities, and trunk. Some children also have arthritis. The syndrome may be idiopathic or secondary to malignancy, Behçet syndrome (see Chapter 151), or chronic recurrent multifocal osteomyelitis (see Chapter 674). Skin biopsy reveals neutrophilic perivascular infiltrates. The condition is usually responsive to treatment with corticosteroids.

Hypertrophic Osteoarthropathy.

Some children with clubbing develop soft tissue swelling over the hands, particularly the distal digits, with arthritis in the distal interphalangeal joints and tender periosteal new bone formation along tubular long bones and bones in the hand. This complication, hypertrophic osteoarthropathy (HOA), can be found in some children with chronic pulmonary disease (e.g., cystic fibrosis), congenital heart disease, gastrointestinal diseases (e.g., malabsorption syndromes, biliary atresia, and inflammatory bowel disease), and malignancies (e.g., nasopharyngeal sarcoma, osteosarcoma, and Hodgkin disease). Although the cause is unknown, some studies suggest that in diseases underlying HOA, platelet fragments escape the pulmonary circulation and interact with peripheral endothelial cells and other tissues. The resulting release of fibroblast and related growth factors causes the clinical manifestations. The symptoms of HOA may improve if the underlying condition can be successfully treated. Evaluation of children presenting with HOA should include a chest radiograph to eliminate pulmonary disease or intrathoracic mass.

Plant Thorn Synovitis.

Puncture wounds due to plant thorns or similar foreign objects that penetrate the synovium can cause acute synovitis that may progress to chronic arthritis. The episode of initial trauma often is forgotten. The diagnosis should be considered in children with chronic monoarticular arthritis unresponsive to anti-inflammatory medication. Diagnosis may require MRI or arthroscopy. Histology often reveals a granulomatous synovitis. Treatment is removal of the foreign body, which may be accomplished by irrigation of the joint during arthroscopy. Chronic synovitis may require synovectomy.

Diabetic Mellitus and Arthropathy.

Diabetic cheiroarthropathy (arthropathy of the joints of the hands and fingers) is a complication of juvenile-onset diabetes mellitus, which occurs most often in late childhood or adolescence. The soft tissues of the hands and fingers undergo progressive thickening and tightening, leading to contractures of the small joints in the hand but without the tapering and loss of digital pulp over the fingertips characteristic of sclerodactyly seen in patients with scleroderma (Chapter 161). Occupational therapy can improve loss of motion in affected joints. Diabetic cheiroarthropathy must be distinguished from polyarticular juvenile rheumatoid arthritis, which can coexist with unrelated chronic conditions and in which joint swelling typically precedes flexion contractures.

Cystic Fibrosis and Arthropathy.

In addition to hypertrophic osteoarthropathy, some patients with cystic fibrosis experience either episodic or persistent arthritis. The cause is unknown but may reflect synovitis resulting from deposition of immune complexes formed in response to recurrent pulmonary infections. It is also possible that persistent arthritis is a result of expression of coexisting, unrelated juvenile rheumatoid arthritis.

Acute Pancreatitis and Arthritis.

Periostitis, nodular skin lesions, and synovial fat necrosis may develop as a result of lipases released during pancreatitis. Affected children may have fever, arthritis, and bone pain for several weeks after blunt abdominal trauma (including child abuse) or other causes of pancreatitis. Elevated serum lipase and amylase levels, periosteal new bone formation, and abnormal findings on bone scintigraphy (revealing fat-induced infarcts) may be found. Drainage of pancreatic pseudocysts may alleviate symptoms of arthritis in some patients.

Immunodeficiency.

Some children with B- and T-lymphocyte immunodeficiencies develop rheumatic diseases. There are several potential mechanisms. Defective mucosal immunity in children with B-cell diseases (e.g., IgA deficiency, X-linked agammaglobulinemia, and common variable immunodeficiency) may permit entry from the gut into the circulation of viruses that are either cross-reactive with self antigens or capable of causing infective synovitis. T-cell defects may result in the loss of T-lymphocyte control over autoreactive T lymphocytes. Arthritis, both episodic and chronic, has been described in children with various types of hypogammaglobulinemia, IgA deficiency, and DiGeorge syndrome. IgA deficiency has also been associated with other rheumatic diseases, including lupus, dermatomyositis, scleroderma, and spondyloarthropathy. Patients with Wiskott-Aldrich syndrome have been reported to develop arthritis, vasculitis, and other rheumatic manifestations. The differential diagnosis of arthritis in children with immunodeficiencies includes suppurative arthritis and osteomyelitis.

Part 16 - Infectious Diseases

Section 1 - *General Considerations*

Chapter 160 - Diagnostic Microbiology

Anita K. M. Zaidi
Donald A. Goldmann

Laboratory diagnosis of infectious diseases is based on one or more of the following: (1) direct examination of specimens by microscopic or antigenic techniques, (2) isolation of microorganisms in culture, (3) serologic testing for development of antibodies (**serodiagnosis**), and (4) molecular genetic detection. Clinicians must select the appropriate tests and specimens and, when possible, suggest the suspected etiologic agents to the microbiologist, who facilitates selection of the most cost-effective diagnostic approach. Additional roles of the microbiology laboratory include antimicrobial susceptibility testing and assisting the hospital epidemiologist in detecting and clarifying the epidemiology of nosocomial infections.

LABORATORY DIAGNOSIS OF BACTERIAL AND FUNGAL INFECTIONS

Diagnosis of bacterial and fungal infections relies mainly on direct demonstration of the microorganisms by microscopic examination or antigen detection and on growth of microorganisms on nutrient culture media. Molecular diagnostic methods for direct detection of some pathogens have also been developed.

Microscopy.

The **Gram stain** remains an extremely useful diagnostic technique because it is a rapid, inexpensive method for demonstrating the presence of bacteria and fungi, as well as inflammatory cells. A preliminary assessment of the etiologic agent can be made by noting the morphology of the microorganisms (e.g., cocci vs rods) and their color (gram-positive microorganisms stain blue, and gram-negative stain red). The presence of inflammatory and epithelial cells can be used to gauge the quality of certain specimens. For example, 10 or more epithelial cells per low-power field in a sputum sample strongly suggests contamination from oral secretions. In many cases, such as in the examination of cerebrospinal fluid (CSF), the Gram stain can provide very rapid and useful results. However, the Gram stain is an insensitive technique, requiring 10^{4-5} microorganisms/mL for detection of organisms. A trained observer may be able to reach a tentative conclusion that there are specific microorganisms in the specimen based on their morphology and Gram reaction (e.g., gram-positive cocci in clusters are likely to be staphylococci), but such preliminary interpretations should be made cautiously and must be confirmed by culture. Many different stains are used in clinical microbiology (Table 160–1).

Rapid Antigen Detection.

Several rapid antigen detection tests for bacterial pathogens are commercially available and widely used. These include **latex agglutination** (LA) tests for detection of group A *Streptococcus* in the pharynx, and *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, group B *Streptococcus*, and *Neisseria meningitidis* in CSF. Routinely performing LA tests on CSF is expensive and offers no advantage over a properly performed Gram stain; their use is best limited to patients with CSF pleocytosis who have received prior antimicrobial therapy.

A rapid and sensitive test for the detection of *Streptococcus pneumoniae* (pneumococcus) antigen in the urine of patients with invasive pneumococcal disease (Binax NOW Urinary Antigen Test, Binax Inc., Portland, ME) has recently become available in the United States. Initial data also indicate utility in the detection of pneumococcal antigen in CSF of patients with meningitis. A major limitation of the urinary test is that approximately half of all well children who are merely nasopharyngeal carriers of pneumococci also test positive.

Isolation and Identification.

Most medically important bacteria can be cultured on nutrient-rich media such as blood agar and chocolate agar. Specialized agar may be used selectively to grow and differentiate among organisms of different types. For example, MacConkey's agar supports growth of gram-negative rods while suppressing gram-positive organisms; a color change in the media from clear to pink distinguishes lactose-fermenting organisms from other gram-negative rods. Liquid broth media are used for blood cultures and to enhance growth of small numbers of organisms in other clinical specimens. Sabouraud's dextrose agar (with antibiotics to inhibit bacterial growth) is used to culture most fungi. However, many pathogens such as *Bartonella*, *Bordetella pertussis, Brucella*, *Francisella*, *Legionella*, anaerobes, mycobacteria, certain fungal pathogens such as *Malassezia furfur, Mycoplasma*, and *Chlamydia* require specialized growth media or incubation conditions. Consultation with the laboratory is advised when these pathogens are suspected and cultures are desired.

After isolation in culture, microbial identity can be confirmed by biochemical tests, ability of the organism to grow in the presence of certain substances that inhibit growth of other microorganisms (e.g., selective antibiotics, salt, bile), antigen detection, or molecular probes.

Blood Culture.

Several different blood culture systems are available; most use 50–100?mL bottles containing broth that enhances the growth of bacteria and fungi (mainly yeast). Bottles with smaller volumes are also available specifically for pediatric use. Media containing resins are often used to adsorb antibiotics to improve recovery of organisms if the patient has received antibiotics before blood culture. Many laboratories use automated culture systems that greatly reduce the time to microbial detection; more than 80% of all cultures containing pathogens are positive at 24 hours of incubation or sooner.

Proper skin disinfection before blood collection is essential. Povidone-iodine may be used, but this agent must be allowed to dry completely for maximum activity. Alcohol is rapidly bactericidal and is a suitable alternative agent. Iodine is effective but must be

TABLE 160-1 -- Stains Used for Microscopic Examination

Type of Stain	Clinical Use
Gram stain	Stains bacteria, fungi, leukocytes, and epithelial cells.
Potassium hydroxide (KOH)	A 10% KOH solution dissolves cellular and organic debris and facilitates detection of fungal elements.
Calcofluor white stain	Nonspecific fluorochrome that binds to cellulose and chitin in fungal cell walls. Can be combined with 10% KOH to dissolve cellular material.
Ziehl-Neelson and Kinyoun stains	Acid-fast stains, using basic carbol fuchsin, followed by acid-alcohol decolorization and methylene blue counterstaining. Acid-fast organisms (e.g., *Mycobacterium*, *Cryptosporidium*, and *Cyclospora*) resist decolorization and stain pink or red. A weaker decolorizing agent is used for partially acid-fast organisms (e.g., *Nocardia*).
Acridine orange stain	Fluorescent dye that intercalates into DNA. At acid pH, bacteria and fungi stain orange, and background cellular material stains green.

Auramine-Rhodamine stain	Acid-fast stain using fluorochromes that bind to mycolic acid in mycobacterial cell walls, and resist acid-alcohol decolorization.
	Acid-fast organisms stain orange-yellow against a black background.
India ink stain	Detects *Cryptococcus neoformans*, an encapsulated yeast, by excluding ink particles from the polysaccharide capsule. (Direct testing for cryptococcal antigen in specimens is much more sensitive than India ink preparations).
Methenamine silver stain	Stains fungal elements, *Pneumocystis* cysts in tissues. Primarily performed in surgical pathology laboratories.
Lugol's iodine stain	Added to wet preparations of fecal specimens for ova and parasites to enhance contrast of the internal structures (nuclei, glycogen vacuoles).
Wright and Giemsa stains	Primarily for detecting blood parasites (*Plasmodium, Babesia*, and *Leishmania*), fungi in tissues (yeasts, *Histoplasma*).
Trichrome stain	Stains stool specimens for identification of protozoa.
Direct fluorescent-antibody stain	Used for direct detection of a variety of organisms in clinical specimens by using specific fluorescein-labeled antibodies (e.g., *Bordetella pertussis*, *Legionella*, *Chlamydia trachomatis*, *Pneumocystis carinii*, many viruses).

wiped off with alcohol to avoid skin reactions. The practice of obtaining blood for culture from intravascular catheters without accompanying peripheral venous blood cultures should be discouraged because it is difficult to determine the significance of coagulase-negative staphylococci and other skin flora isolated from blood obtained from “through-the-line” cultures. For patients with suspected bacteremia and fungemia, two or three separate blood cultures are preferred. More than three blood cultures rarely are indicated, even in infective endocarditis. Whenever possible, a minimum of 2?mL of blood should be obtained for culture before administration of antibiotics. Obtaining a larger volume of blood is necessary to maximize yield from blood cultures, because 10–20% of pediatric patients may have low-grade bloodstream infections. For most patients, the most effective approach is to culture the entire volume of blood in a single aerobic bottle because anaerobic bacteremia is rare in children. Blood should also be cultured anaerobically for patients at increased risk for anaerobic sepsis, such as children who are immunocompromised or who have head and neck or abdominal infections. Detection of fungi can be aided by lysis-centrifugation techniques, such as the Isolator 1.5 system (Wampole, Cranbury, NJ). In developing countries with high rates of *Salmonella* bloodstream infections, optimal blood culture practices remain undefined.

CSF CULTURE.

CSF should be transported quickly to the laboratory, where it is centrifuged to concentrate organisms for microscopic examination. CSF is routinely plated on blood agar and chocolate agar, which support the growth of the common pathogens that cause meningitis. If tuberculous meningitis is suspected, CSF cultures for mycobacteria should be specifically requested.

URINE CULTURE.

Urine for culture and colony count can be obtained by collecting clean-voided midstream specimens, catheterization, or suprapubic aspiration. Urine samples collected by placing bags on the perineum are unacceptable for culture because of frequent contamination, which renders the results uninterpretable. Rapid transport of urine to the laboratory is imperative because gram-negative enteric pathogens have doubling times of 20–30?min, and any delay in transport or plating renders colony counts unreliable. Refrigeration can be used when delay is unavoidable. Culture systems using media-coated “paddles” permit prompt inoculation of the specimen, but confluent growth may be difficult to detect; moreover, accurate antibiotic susceptibility testing requires the presence of individual discrete colonies. Urine obtained by suprapubic puncture should normally be sterile; any bacterial growth is considered significant. Urine colony counts are generally considered significant in urine collected by catheterization if 10^3 organisms/mL or greater, and in urine collected by clean-catch (midstream) void if 10^5 organisms/mL or greater are present. However, lower counts are sometimes found in urinary tract infections in adolescent girls and young women, especially those with bacterial urethritis, or in patients with fungal infections. A Gram stain of unspun urine with at least one bacterium per oil immersion field correlates well with the presence of greater than or equal to 10^5 organisms/mL of urine.

GENITAL TRACT CULTURE.

Specimens from the genital tract include urethral, cervical, and anorectal swabs. *Neisseria gonorrhoeae* organisms are fragile, and rapid inoculation at the bedside onto Thayer-Martin medium (warmed to room temperature) or one of its modifications is crucial. Ordinarily, cultures for sexually transmitted pathogens should include specimens obtained from genital, anorectal, and pharyngeal sources to achieve maximum yield. Specimens for *Chlamydia trachomatis* culture are obtained by cotton-tipped, aluminum-shafted urethral swabs. Endocervical specimens, using swabs with aluminum or plastic shafts, should be collected by rubbing the swab vigorously against the endocervical wall to obtain as much cellular material as possible. *C. trachomatis* is cultured by inoculation into cell culture systems, followed by immunofluorescent staining with monoclonal antibody against the organism. However, nonculture methods, such as enzyme immunoassay (EIA) tests, direct immunofluorescent staining by monoclonal antibodies, and DNA amplification methods are widely used and tend to be more cost effective than culture.

THROAT AND RESPIRATORY TRACT CULTURES.

Obtaining a throat swab for culture is the most reliable method of diagnosing group A streptococcal pharyngitis and tonsillitis. Vigorous swabbing of the tonsillar area and posterior pharynx is necessary for maximum recovery, but even optimal specimens detect only approximately 90% of infections. The pharynx contains many normal flora; thus, most laboratories screen cultures only for the presence of group A ß-hemolytic *Streptococcus*. Some laboratories do not use selective procedures, however, and often report the presence of meningococci, which are usually

nontypable and nonpathogenic strains, but occasionally report typable meningococci and other potential pathogens. Most patients harboring such bacteria are carriers, and the culture report serves only to create undue alarm. The laboratory should be alerted when diphtheria, pertussis, gonococcal pharyngitis, or infection with *Arcanobacterium haemolyticum* is clinically suspected. Cultures for *B. pertussis* are obtained by aspiration or a Dacron or flexible wire calcium alginate swab (Calgiswab) of the nasopharynx and inoculation onto special charcoal-blood (Regan-Lowe) or Bordet-Gengou media.

The cause of lower respiratory tract disease in children is not easy to confirm microbiologically because of difficulty in obtaining adequate sputum specimens and lack of correlation between upper respiratory tract flora and organisms causing lower respiratory tract disease. Specimens showing large numbers of epithelial cells or few neutrophils on Gram stain are unsuitable for culture. Patients with cystic fibrosis can usually provide adequate expectorated sputum, and special media should be used to detect important cystic fibrosis pathogens such as *Burkholderia cepacia*.

Endotracheal aspirates from intubated patients may be useful if the Gram stain shows abundant neutrophils and bacteria, although pathogens recovered from such specimens may still reflect only contamination from the endotracheal tube or upper airway. Quantitative cultures of bronchoalveolar lavage fluid or bronchial brush specimens may be valuable for distinguishing upper respiratory tract contamination from lower tract disease in special circumstances.

The diagnosis of pulmonary tuberculosis in young children is best confirmed by culture of early morning gastric aspirates, obtained on 3 successive days, rather than by sputum cultures. Acid-fast stains of gastric aspirates from children with pulmonary tuberculosis are rarely positive. Cultures for *Mycobacterium tuberculosis* should be processed only in laboratories equipped with appropriate biologic safety cabinets and containment facilities.

STOOL CULTURE.

Most laboratories in North America routinely culture stool for the presence of *Salmonella, Shigella*, and *Campylobacter* by inoculation onto **selective agar** (to decrease the growth of normal fecal flora) and **differential agar** (to help distinguish pathogenic enteric flora from normal enteric flora). Freshly passed stool is preferred for culture, but rectal swabs may be acceptable. Cultures for *Escherichia coli* O157:H7, *Vibrio cholerae, Yersinia enterocolitica, Aeromonas*, and *Plesiomonas* should be specifically requested when these organisms are suspected. Isolation of enterotoxigenic *E. coli*, the most common cause of traveler's diarrhea, and other pathogenic types of *E. coli*, except for *E. coli* O157:H7, is not routinely attempted. Bacterial stool cultures in the United States rarely yield useful results in patients who have been hospitalized for more than 3 days. Culture for *Clostridium difficile*, the most common bacterial cause of nosocomial diarrhea, has largely been replaced by tests that detect toxin production, such as cell culture assays for cytotoxicity, or EIAs.

CULTURE OF OTHER FLUIDS AND TISSUES.

Abscesses, wounds, pleural fluid, peritoneal fluid, joint fluid, and other purulent fluids are cultured onto routine solid agar and broth media. Whenever possible, fluid rather than swabs from infected sites should be sent to the laboratory because culture of a larger volume of fluid may detect organisms present in low concentration. The yield from joint fluid cultures in patients with suppurative arthritis may be increased by inoculation into broth-containing blood culture bottles. Anaerobic organisms are involved in many abdominal and wound abscesses. These specimens should be collected and transported rapidly under anaerobic conditions, preferably in anaerobic transport tubes.

Antimicrobial Susceptibility Testing.

Antimicrobial susceptibility tests are generally performed on all organisms of clinical significance except for a few that have predictable antimicrobial susceptibility patterns, such as group A *Streptococcus*, which is currently universally susceptible to penicillin. The most common technique is the **agar disk diffusion method (Bauer-Kirby method)**, in which a standardized inoculum of the organism is seeded onto an agar plate. Antibiotic-impregnated filter paper disks are then placed on the agar surface. After 18–24?hr of incubation, the zone of inhibition of bacterial growth around each disk is measured and compared with nationally determined standards for susceptibility or resistance.

The other widely used technique for susceptibility testing is **dilution testing**, in which a standard concentration of a microorganism is inoculated into serially diluted concentrations of antibiotic, and the **minimum inhibitory concentration (MIC)** in µg/mL, the lowest concentration of antibiotic required to inhibit growth of the microorganism, is determined. Dilution testing also permits determination of the **minimum bactericidal concentration (MBC)**, the lowest concentration of antibiotic required to kill the organism. The MBC is sometimes determined to exclude the possibility of **bacterial tolerance** (MBC > 4 times the MIC). Automated methods that use microtiter wells with pre-made dilutions of antibiotics are now used commonly. However, MICs from automated systems should be interpreted with caution for certain pathogen-antibiotic combinations (e.g., pneumococci resistant to penicillin, enterococci with low-level resistance to vancomycin). Screening agar plate tests, such as oxacillin disk susceptibility to detect penicillin-resistant pneumococci, followed by confirmatory tests, are recommended. The **E-test** is a new method of measuring MICs of individual antibiotics on an agar plate that uses a paper strip impregnated with a known continuous concentration gradient of antibiotic that diffuses across the agar surface, inhibiting microbial growth in an elliptic zone. The MIC is read off the printed strip at the point at which the zone intersects the strip. Major advantages of the E-test are reliable interpretation, reproducibility, and applicability to organisms that require special media or growth conditions, including anaerobic bacteria. However, the cost precludes its use as the principal testing system in clinical laboratories.

Office Bacteriology.

Many office practices perform rapid antigen testing for detection of group A streptococcal pharyngitis. The sensitivity depends on the type of kit used and on the concentration of streptococci present in the sample, and as many as 30% of test results may be false-negative. Therefore, all negative results of antigen testing for group A *Streptococcus* should be confirmed by culture.

Other microbiologic tests may be performed in the office setting as long as the site is certified as meeting appropriate quality assurance standards specified by the Clinical Laboratory Improvement Amendments (CLIA) Act of 1988. These include procedures listed under the category of "physician-performed microscopy" including wet mounts, potassium hydroxide (KOH) preparations, pinworm examinations, fecal leukocyte examinations, and urine sediment analysis. Office laboratories licensed for this category are limited to performing these tests but avoid having to undergo periodic inspections and proficiency testing, although they are still subject to CLIA certification requirements specific to these tests. Gram staining, culture inoculation, and isolation of bacteria are considered moderately to highly complex tests under CLIA specifications. Any office laboratory performing Gram stains or cultures must comply with the same requirements and inspections for quality assurance, proficiency testing, and personnel requirements as fully licensed microbiology laboratories.

LABORATORY DIAGNOSIS OF VIRAL INFECTIONS

Specimens for viral diagnosis are selected on the basis of knowledge of the site that is most likely to yield the suspected pathogen. Specimens should be collected early in the course of infection when viral shedding is maximal. Fluids and respiratory secretions should be collected in sterile containers and delivered to the laboratory promptly. Swabs should be rubbed vigorously against mucosal or skin surfaces to obtain as much cellular material as possible, and sent in viral transport media that contain antibiotics to inhibit bacterial growth. Rectal swabs should not be heavily covered with feces because the antibiotics present in viral transport media may be insufficient to kill a large inoculum of bacteria. All specimens for virus culture should be transported on ice. Freezing specimens can result in a significant decrease in culture sensitivity. Consultation with the laboratory is advised for any unusual specimens or suspected pathogens.

Laboratory diagnosis of viral infections may be performed by electron microscopy, antigen detection, virus isolation in culture, serologic testing, or detection of virus genomes by molecular biology techniques. Serologic and molecular tests are the mainstay of diagnosis of viruses such as HIV and Epstein-Barr virus (EBV).

Rapid Antigen Tests.

Immunofluorescent-antibody (IFA) techniques or other methods such as EIA that use antibodies to detect viral antigens directly in clinical specimens permit rapid identification of viruses. For example, smears of cellular material from respiratory secretions stained by immunologic reagents can identify the antigens of respiratory syncytial virus (RSV), adenovirus, influenza virus, and parainfluenza virus within 2–3?hr after the specimen is received. In comparison with isolation in cell culture, IFA is approximately 95% sensitive and 98% specific for the diagnosis of RSV and parainfluenza virus type 3 in reference laboratories; the sensitivity of IFA for influenza viruses and adenoviruses is considerably lower. Sensitive IFA staining techniques are also commercially available for identification of varicella-zoster virus (VZV) and herpes simplex virus (HSV). These specific methods have supplanted the Tzanck smear for multinucleated giant cells characteristic of VZV or HSV infections. Several methods for detecting cytomegalovirus (CMV) antigen in blood of high-risk patients also have been developed. IFA is not useful for detecting virus in specimens that do not contain an adequate number of infected cells. When possible, an accompanying specimen for virus isolation usually is advisable.

In addition to providing rapid diagnosis, antigen detection EIA tests are commonly used for the diagnosis of viruses that are difficult or impossible to culture, such as rotavirus, Norwalk virus, and hepatitis B virus.

Isolation and Identification.

Viruses require living cells for propagation; the cells used most often are human or animal-derived tissue culture monolayers, such as human embryonic lung fibroblasts or monkey kidney cells. In vivo methods for isolation are sometimes necessary (e.g., suckling mice inoculation for culture of arboviruses and rabies virus). Because viruses require various cell culture systems for isolation, it is important for clinicians to provide relevant clinical information to the laboratory to facilitate inoculation of appropriate cell lines.

Viral growth in susceptible cells can be detected in several ways. Many viruses produce a characteristic **cytopathic effect (CPE)** that is discernible in cell culture by light microscopy under low magnification. For example, RSV and HSV produce multinucleated giant cells and syncytia formation. Other viruses (e.g., influenza virus and mumps virus) can be detected by hemadsorption because hemagglutinins on infected cell membranes facilitate adherence of erythrocytes to infected cells. The most reliable confirmatory method for viral detection in cell culture involves staining cell monolayers with monoclonal antibodies to virus antigens, which are conjugated with a fluorescent or enzyme substrate to permit identification of antigen-antibody binding.

LABORATORY DIAGNOSIS OF PARASITIC INFECTIONS

Most parasites are detected by microscopic examination of clinical specimens. For example, *Plasmodium* and *Babesia* can be detected in stained blood smears, *Leishmania* in bone marrow smears, and helminth eggs, *Entamoeba histolytica* and *Giardia lamblia* cysts, and trophozoites in fecal smears (see Table 160–1). Serologic tests are important in documenting exposure to certain parasites that are difficult to demonstrate in clinical specimens, such as *Trichinella* and *Toxoplasma*. Serologic testing also has a role in the diagnosis of intestinal strongyloidiasis, given the insensitivity of stool examinations.

Fecal specimens should not be contaminated with water or urine because water may contain free-living organisms that can be confused with human parasites, and urine

may destroy motile organisms. Mineral oil, barium, and bismuth interfere with the detection of parasites; specimen collection should be delayed for 7–10 days after ingestion of these substances. Because *Giardia* and many worm eggs are shed intermittently into feces, a minimum number of three specimens is required for an adequate examination. The three specimens should be collected on separate days, preferably on alternate days. Because many protozoan parasites are easily destroyed, collection kits with stool preservatives should be used if delay between specimen collection and transport to the laboratory is anticipated.

Ova and parasite examination of fecal specimens includes a wet mount (to detect motile organisms if fresh stool is received), concentration (to improve yield), and permanent staining, such as trichrome, for microscopic examination. These techniques may miss parasites such as *Cryptosporidium, Cyclospora*, and microsporidia (*Enterocytozoon bieneusi* and *Septata intestinalis*). *Cryptosporidium* and *Cyclospora* are detected by modified acid-fast stain and microsporidia by a modification of the trichrome stain. The laboratory should be notified if these parasites are suspected. Detection of certain parasites, especially *Giardia* and *Cryptosporidium*, can be simplified by using sensitive EIA antigen detection tests.

SEROLOGIC DIAGNOSIS

Serologic tests are used primarily in the diagnosis of infectious agents that are difficult to culture in vitro or detect by direct examination, such as *Bartonella henselae, Legionella, Borrelia burgdorferi* (Lyme disease), *Treponema pallidum, Mycoplasma pneumoniae, Rickettsia, Ehrlichia*, some viruses (HIV, EBV, hepatitis viruses), and parasites (*Toxoplasma, Trichinella*).

Antibody tests may be specific for immunoglobulin G (IgG) or M (IgM), or may measure antibody response regardless of immunoglobulin class. The IgM response occurs earlier in the illness, generally peaking at 7–10 days after infection, and usually disappears within a few weeks, but for some infections (e.g., hepatitis A) may persist for months. The IgG response peaks at 4–6 weeks and in most cases persists for life. Because the IgM response is transient, the presence of IgM antibody in most cases correlates with recent infection; therefore, a single positive serum specimen is considered diagnostic. Methods for IgM antibody detection are difficult to standardize, however, and false-positive results frequently occur with some tests. The presence of IgG antibody may indicate recent seroconversion or past exposure to the pathogen. To confirm a new infection using IgG testing, it is necessary to demonstrate either **seroconversion**, from seronegative to seropositive, or a significant elevation in IgG titer; a fourfold increase in a **convalescent titer** obtained 2–3 wk after the **acute titer** is considered diagnostic in most situations. However, for some infections (e.g., *Bartonella, Legionella*, and rickettsiae) a single positive IgG titer in the appropriate clinical setting is sufficient for diagnosis. The serologic diagnosis of Lyme disease deserves special mention because lack of specificity of the various commercially available enzyme immunoassays remains a problem. To improve specificity, a follow-up confirmatory immunoblot (Western blot) is required for all positive and equivocal results.

MOLECULAR DIAGNOSTIC TECHNIQUES

Molecular diagnostic techniques are most useful for detecting and identifying pathogens for which culture and serologic tests are difficult, slow, or not available. Two of the widely used techniques in clinical microbiology are DNA probes for direct detection and nucleic acid amplification using polymerase chain reaction (PCR).

DNA probes detect or identify organisms by hybridization of the probe to complementary sequences in DNA or ribosomal

RNA. Detection of pathogen nucleic acid directly in clinical specimens requires the presence of relatively large numbers of organisms in the specimen. With the exception of commercially available probes for combined direct detection of *Chlamydia trachomatis* and *Neisseria gonorrhoeae* in the same specimen (e.g., GenProbe PACE2 or Digene Hybrid Capture II CT/GC), the principal use of DNA probe technology remains rapid identification of organisms that already have been isolated in culture but require additional time-consuming or complex confirmation procedures. For example, probes for mycobacterial species can rapidly distinguish *M. tuberculosis* from *M. avium-intracellulare* growing in broth cultures.

The high sensitivity and specificity of PCR amplification make this the method of choice for direct detection of microbial nucleic acid from clinical specimens. The PCR method is based on the ability of thermostable DNA or RNA polymerase to copy targeted gene sequences using complementary nucleotides as primers to amplify a conserved region of the genome. The reaction takes place in a thermal cycler, and, theoretically, each cycle of the reaction doubles the amount of target nucleic acid, resulting in more than a million-fold amplification in 30 cycles of PCR. The number of pathogens that can be detected by PCR is increasing rapidly. PCR tests are available using commercial reagents for HIV, hepatitis C virus, *M. tuberculosis*, and *C. trachomatis*. Additionally, experimental PCR protocols for detection of *Bartonella, B. pertussis, Legionella, M. pneumoniae, Chlamydia pneumoniae*, HSV, CMV, and EBV are available in some reference laboratories.

Specimens for PCR should be sent in separate sterile containers and transported rapidly to the laboratory. PCR methods are technically complex and labor intensive. False-positive reactions are a major problem because the extreme sensitivity of the assay can lead to amplification of target nucleic acid from extraneous sources or from crossover contamination from other positive specimens. Clinically relevant diagnostic PCR testing should be performed only in reference laboratories using adequate quality control measures.

Chapter 161 - Fever

Keith R. Powell

Fever is a controlled increase in body temperature over the normal values for an individual. Body temperature is regulated by **thermosensitive neurons** located in the preoptic or anterior hypothalamus that respond to changes in blood temperature as well as to direct neural connections with cold and warm receptors located in skin and muscle. **Thermoregulatory responses** include redirecting blood to or from cutaneous vascular beds, increased or decreased sweating, extracellular fluid volume regulation (via arginine vasopressin), and behavioral responses, such as seeking a warmer or cooler environmental temperature. Normal body temperature also varies in a regular pattern each day. This circadian temperature rhythm, or **diurnal variation**, results in lower body temperatures in the early morning and temperatures approximately 1°C higher in the late afternoon or early evening.

Pathogenesis.

Fever is regulated in the same manner as normal temperature is maintained in a cool environment, the difference being that the body's thermostat has been reset at a higher temperature (Fig. 161–1). Regardless of whether fever is associated with infection, rheumatic disease, or malignancy, the thermostat is reset in response to **endogenous pyrogens** including the cytokines interleukin (IL)-1 and IL-6, tumor necrosis factor-a (TNFa), and interferon (IFN)-s and -?. Stimulated leukocytes and other cells produce lipids that also serve as endogenous pyrogens. The best-studied lipid mediator is prostaglandin E_2 . Most endogenous pyrogen molecules are too large to cross the blood-brain barrier in an efficient manner. However, circumventricular organs in close proximity to the hypothalamus lack a blood-brain barrier and allow for neuronal contact with circulating factors through fenestrated capillaries.

Microbes, microbial toxins, or other products of microbes are the most common "exogenous pyrogens," which are substances that come from outside of the body, stimulate macrophages and other cells to produce endogenous pyrogens, and result in fever. Some substances produced within the body are not pyrogens but are capable of stimulating endogenous pyrogens. Such substances include antigen-antibody complexes in the presence of complement, complement components, lymphocyte products, bile acids, and androgenic steroid metabolites.

Endotoxin is one of the few substances that can directly affect thermoregulation in the hypothalamus as well as stimulate endogenous pyrogen release. Fever may be caused by infection, vaccines, biologic agents (e.g., granulocyte-macrophage colony-stimulating factor, interferons, interleukins), tissue injury (e.g., infarction, pulmonary emboli, trauma, intramuscular injections, burns), malignancy (e.g., leukemia, lymphoma, hepatoma, metastatic disease), drugs (e.g., cocaine, amphotericin B, drug fever), immunologic-rheumatologic disorders (e.g., systemic lupus erythematosus, rheumatoid arthritis), inflammatory diseases (e.g., inflammatory bowel disease), granulomatous diseases (e.g., sarcoidosis), endocrine disorders (e.g., thyrotoxicosis, pheochromocytoma), metabolic disorders (e.g., gout, uremia, Fabry disease, type 1 hyperlipidemia), genetic disorders (e.g., familial Mediterranean fever), and unknown or poorly understood entities. **Factitious fever**, or self-induced fever, may be due to intentional manipulation of the thermometer or injection of pyrogenic material.

Increasing body temperature in response to microbial pathogens is a response observed in reptiles, fish, birds, and mammals. When fish are given an exogenous pyrogen, they swim to warmer water to raise their body temperature. In a similar fashion, lizards given exotoxin lie in the sun until they have raised their body temperature to the febrile range. In humans, increased temperatures

Figure 161-1 The pathogenesis of fever. Various infectious toxins and other mediators induce the production of endogenous pyrogens by host inflammatory cells. Endogenous pyrogens include the cytokines interleukin (IL)-1 and IL-6, tumor necrosis factor-a (TNFa), and interferon (IFN)-s and -?. Endogenous pyrogenic cytokines directly stimulate the hypothalamus to produce prostaglandin (PG) E_2 (PGE_2), which then resets the temperature regulatory set point. Neuronal transmission from the hypothalamus leads to conservation and generation of heat, thus raising core body temperature. (From Dinarello CA, Cannon JG, Wolff SM: New concepts on the pathogenesis of fever. *Rev Infect Dis* 1988;10: 168–89.)

are associated with decreased microbial reproduction and an increased inflammatory response. Thus, most evidence suggests that fever is an adaptive response and should be treated only in selected circumstances. Heat production associated with fever increases oxygen consumption, carbon dioxide production, and cardiac output. Thus, fever may exacerbate cardiac insufficiency in patients with heart disease or chronic anemia (e.g., sickle cell disease), pulmonary insufficiency in those with chronic lung disease, and metabolic instability in children with diabetes mellitus or inborn errors of metabolism. Furthermore, children between the ages of 6 mo and 5 yr are at increased risk of benign febrile seizures, whereas those with idiopathic epilepsy may have an increased frequency of seizures associated with a febrile illness (see Chapter 586.3).

Clinical Manifestations.

Although fever patterns per se are not often helpful in determining a specific diagnosis, observing the clinical characteristics of fever can provide useful information. In general, a single isolated fever spike is not associated with an infectious disease. Such a spike can be attributed to the infusion of blood products, some drugs, some procedures, or manipulation of a catheter on a colonized or infected body surface. Similarly, temperatures in excess of 41°C are most often associated with a noninfectious cause. Causes of very high temperatures (>41°C) include **central fever** (resulting from central nervous system dysfunction involving the hypothalamus), malignant hyperthermia, malignant neuroleptic syndrome, drug fever, or heatstroke. Temperatures that are lower than normal (<36°C) can be associated with overwhelming sepsis but are more commonly related to cold exposure, hypothyroidism, or overuse of antipyretics.

Intermittent fever is an exaggerated circadian rhythm that includes a period of normal temperatures on most days; extremely wide fluctuations may be termed **septic or hectic fever. Sustained fever** is persistent and does not vary by more than 0.5°C/24?hr. **Remittent fever** is persistent and varies by more than 0.5°C/24. **Relapsing fever** is characterized by febrile periods that are separated by intervals of normal temperature; **tertian fever** occurs on the 1st and 3rd days (e.g., malaria caused by *Plasmodium vivax*), and **quartan fever** occurs on the 1st and 4th days (e.g., malaria caused by *Plasmodium malariae*). Diseases characterized by relapsing fevers (Box 161–1) should be distinguished from those infectious diseases that have a tendency to relapse. A **biphasic fever** indicates a single illness with two distinct periods of fever over 1 or more weeks (camelback fever pattern); poliomyelitis is the classic example. A biphasic course is also characteristic of leptospirosis, dengue fever, yellow fever, Colorado tick fever, spirillary rat-bite fever (*Spirillum minus*), and the African hemorrhagic fevers (Marburg, Ebola, and Lassa fever). **Periodic fever** is used narrowly to describe fever syndromes with a regular periodicity (e.g., cyclic neutropenia, and periodic fever, aphthous stomatitis, pharyngitis, and adenopathy [PFAPA]) or more broadly to include disorders characterized by recurrent episodes of fever that do not follow a strictly periodic pattern (e.g., familial Mediterranean fever, Hibernian fever, and hyper IgD syndrome).

The relationship between a patient's pulse rate and temperature can be informative. **Relative tachycardia**, when the pulse rate is elevated out of proportion to the temperature, is usually due to noninfectious diseases or infectious diseases in which a toxin is responsible for the clinical manifestations. **Relative bradycardia (temperature-pulse dissociation)**, when the pulse rate remains low in the presence of fever, suggests typhoid fever, brucellosis, leptospirosis, or drug fever. Bradycardia in the presence of fever also may be a result of a conduction defect resulting from cardiac involvement with acute rheumatic fever, Lyme disease, viral myocarditis, or infective endocarditis.

Box 161-1. Fevers Prone to Relapse

INFECTIOUS CAUSES

- Relapsing fever (*Borrelia recurrentis*)
- Trench fever (*Rochalimaea quintana*)
- Q Fever (*Coxiella burnetii*)
- Typhoid fever (*Salmonella typhi*)
- Syphilis (*Treponema pallidum*)
- Tuberculosis
- Histoplasmosis
- Coccidioidomycosis
- Blastomycosis
- Melioidosis (*Pseudomonas pseudomallei*)
- Lymphocytic choriomeningitis (LCM) virus
- Dengue fever
- Yellow fever
- Chronic meningococcemia
- Colorado tick fever
- Leptospirosis
- Brucellosis
- Oroya fever (*Bartonella bacilliformis*)
- Acute rheumatic fever
- Rat-bite fever (*Spirillum minus*)
- Visceral leishmaniasis
- Lyme disease (*Leptospira burgdorferi*)
- Malaria

- Visceral leishmaniasis
- Lyme disease (*Leptospira burgdorferi*)
- Malaria

- Babesiosis
- Noninfluenza respiratory viruses
- Epstein-Barr virus

NONINFECTIOUS CAUSES

- Behçet disease
- Crohn disease
- Weber–Christian disease (panniculitis)
- Leukoclastic angiitis
- Sweet's syndrome
- Systemic lupus erythematosus

PERIODIC FEVER SYNDROMES

- Familial Mediterranean fever
- Cyclic neutropenia
- Periodic fever, aphthous stomatitis, pharyngitis, adenopathy
- (PFAPA)
- Hyper IgD syndrome
- Hibernian fever

Modified from Cunha BA: The clinical significance of fever patterns. Infect Dis Clin North Am 1996;10:33–44.

Most infections result in some type of injury that induces an inflammatory response and subsequently results in the release of endogenous pyrogens. Administration of

antimicrobial agents can result in a very rapid elimination of bacteria, but if tissue injury has been extensive, the inflammatory response and fever can continue for days after all microbes have been eradicated.

Treatment.

Fever with temperatures less than 39°C in healthy children generally do not require treatment. As temperatures become higher, patients tend to become more uncomfortable and administration of antipyretics often makes patients feel better. Other than providing symptomatic relief, antipyretic therapy does not change the course of infectious diseases. Antipyretic therapy is beneficial in high-risk patients who have chronic cardiopulmonary diseases, metabolic disorders, or neurologic diseases and in those who are at risk for febrile seizures. Hyperpyrexia (>41°C) indicates greater risk of severe infection, hypothalamic disorders, or central nervous system hemorrhage, and should always be treated with antipyretics. High fever during pregnancy may be teratogenic.

Acetaminophen, aspirin, and ibuprofen are inhibitors of hypothalamic cyclooxygenase, thus inhibiting PGE_2 synthesis. These drugs all are equally effective antipyretic agents. Because aspirin has been associated with Reye syndrome in children and adolescents, its use is not recommended for the treatment of fever. Acetaminophen, 10–15?mg/kg orally every 4?hr, is not associated with significant adverse effects; however, prolonged use may produce renal injury, and massive overdose may produce hepatic failure. Ibuprofen, 5–10?mg/kg orally every 6–8?hr, may cause dyspepsia, gastrointestinal bleeding, reduced renal blood flow, and rarely, aseptic meningitis, hepatic toxicity, or aplastic anemia. Serious injury from ibuprofen overdose is unusual. Tepid sponge bathing in warm water (not alcohol) is another recommended method of reducing hyperpyrexia due to infection or hyperthermia resulting from external causes (e.g., heatstroke). The decline of body temperature after antipyretic therapy does not distinguish serious bacterial from less serious viral diseases.

Chapter 162 - Fever Without a Focus

Keith R. Powell

Fever is a common manifestation of infectious diseases but is not predictive of severity. Many common viral (e.g., rhinitis, pharyngitis, pneumonia) and bacterial (e.g., otitis media, pharyngitis, impetigo) infections are usually benign in normal hosts and respond well to appropriate antimicrobial or supportive therapy. Other infections (e.g., sepsis, meningitis, pneumonia, osteoarticular infections, pyelonephritis), if untreated, may have significant morbidity or mortality. Most febrile episodes in a normal host can be diagnosed by a careful history and physical examination and require few if any laboratory tests. However, there are well-defined high-risk groups that, on the basis of age, associated diseases, or immunodeficiency status, require a more extensive evaluation and, in certain situations, prompt antimicrobial therapy before a pathogen is identified (Table 162–1).

FEVER WITHOUT LOCALIZING SIGNS

Fever without localizing signs or symptoms, usually of acute onset and present for less than 1 wk, is a common diagnostic dilemma for pediatricians caring for children younger than 36 mo of age. Infants younger than 4 wk of age may acquire community pathogens but are also at risk for late-onset neonatal bacterial diseases and perinatally acquired herpes simplex virus infection. Young infants demonstrate limited signs of infection, often making it difficult to distinguish clinically between serious bacterial infections and self-limited viral illnesses.

Infants Younger than 3 mo of Age.

An infectious agent, usually viral, is identified in 70% of infants younger than 3 mo of age with fever; the remainder are presumed to have self-limited but undiagnosed viral infections. However, fever in an infant younger than 3 mo of age should always suggest the possibility of serious bacterial disease. Serious bacterial infections are present in 10–15% of previously healthy term infants presenting with rectal temperatures of 38°C or greater. These infections include sepsis, meningitis, urinary tract infections, enteritis, osteomyelitis, and suppurative arthritis. Bacteremia is present in 5% of febrile infants younger than 3 mo of age; organisms

TABLE 162-1 -- **Febrile Patients at Increased Risk for Serious Bacterial Infections**

Risk Group	Diagnostic Considerations
Immunocompetent Patients	
Neonates (<28 days)	Sepsis and meningitis caused by group B *Streptococcus*, *Escherichia coli*, *Listeria monocytogenes*, and herpes simplex virus
Infants <3 mo	Serious bacterial disease in 10–15%, including bacteremia in 5%, of febrile infants <3 mo
Infants and children 3–36 mo	Occult bacteremia in 1.5%; increased risk with temperature >39°C and white blood cell count >15,000/µL
Hyperpyrexia (>40°C)	Meningitis, bacteremia, pneumonia, heatstroke, hemorrhagic shock–encephalopathy syndrome
Fever with petechiae	Bacteremia and meningitis caused by *Neisseria meningitidis*, *Haemophilus influenzae* type b, and *Streptococcus pneumoniae*
Immunocompromised Patients	
Sickle cell disease	Sepsis, pneumonia, and meningitis caused by *S. pneumoniae*, osteomyelitis caused by *Salmonella* (as well as *Staphylococcus*)
Asplenia	Bacteremia and meningitis caused by *N. meningitidis*, *H. influenzae* type b, and *S. pneumoniae*
Complement/properdin deficiency	Sepsis caused by *N. meningitidis*
Agammaglobulinemia	Bacteremia, sinopulmonary infection
AIDS	*S. pneumoniae*, *H. influenzae* type b, and *Salmonella* infections
Congenital heart disease	Infective endocarditis; brain abscess with right-to-left shunting
Central venous line	*Staphylococcus aureus*, coagulase-negative staphylococci, *Candida*
Malignancy	Bacteremia with gram-negative enteric bacteria, *S. aureus*, and coagulase-negative staphylococci; fungemia with *Candida* and *Aspergillus*

responsible for bacteremia include group B *Streptococcus* and *Listeria monocytogenes* (late-onset neonatal sepsis and meningitis) and community-acquired pathogens including *Salmonella* (enteritis), *Escherichia coli* (urinary tract infection),

Neisseria meningitidis, Streptococcus pneumoniae, and *Haemophilus influenzae* type b (sepsis and meningitis), and *Staphylococcus aureus* (osteoarticular infection). Pyelonephritis is more common in uncircumcised infant boys, neonates and infants with urinary tract anomalies, and young girls. Other potential bacterial diseases in this age group include otitis media, pneumonia, omphalitis, mastitis, and other skin and soft tissue infections.

Viral pathogens can be identified in 40–60% of febrile infants younger than 3 mo of age. In contrast to bacterial infections, which have no seasonal pattern, viral diseases have a distinct pattern: respiratory syncytial virus and influenza A virus infections are more common during the winter, whereas enterovirus infections usually occur in the summer and fall.

The approach to febrile patients younger than 3 mo of age includes a careful history and physical examination. Ill-appearing (toxic) febrile infants younger than 3 mo of age require prompt hospitalization and immediate parenteral antimicrobial therapy after cultures of blood, urine, and cerebrospinal fluid (CSF) are obtained. Ceftriaxone (50?mg/kg/dose every 24?hr with normal CSF findings, or 80?mg/kg/dose every 24?hr with CSF pleocytosis) or cefotaxime (50?mg/kg/dose every 6?hr), plus ampicillin (50?mg/kg/dose every 6?hr) to cover for *L. monocytogenes* and *Enterococcus*, is an effective initial antimicrobial regimen for ill-appearing infants without focal findings. This regimen is effective against the usual bacterial pathogens causing sepsis, urinary tract infection, and enteritis in young infants. However, if meningitis is suspected because of CSF abnormalities, vancomycin (15?mg/kg/dose every 6?hr) should be given to cover for possible penicillin-resistant *S. pneumoniae*, in addition to the ceftriaxone/cefotaxime and ampicillin, until the results of culture and susceptibility tests are known.

Infants younger than 3 mo of age with fever who appear generally well; who have been previously healthy; who have no evidence of skin, soft tissue, bone, joint, or ear infection; and who have a total white blood cell (WBC) count of 5,000–15,000 cells/µL, an absolute band count of less than 1,500 cells/µL, and normal urinalysis results are unlikely to have a serious bacterial infection. The negative predictive value with 95% confidence of these criteria for any serious bacterial infection is greater than 98%, and greater than 99% for bacteremia.

Occult Bacteremia in Children 3 Mo–3 Yr of Age.

Approximately 30% of febrile children 3 mo–3 yr of age have no localizing signs of infection. Occult bacteremia (bacteremia without an apparent focus of infection) due to *S. pneumoniae, N. meningitidis*, and *Salmonella* occurs in approximately 1.5% of relatively well-appearing children between 3–36 mo of age with fever (rectal temperature =38.0℃). The increased incidence of bacteremia among young children may be due in part to a maturational immune deficiency in the production of opsonic IgG antibodies to the polysaccharide antigens present on encapsulated bacteria. *S. pneumoniae* accounts for 90% of cases of occult bacteremia, with *N. meningitidis* and *Salmonella* accounting for most of the remaining positive cultures. *H. influenzae* type b was an important cause of occult bacteremia in young children before the universal use of conjugate *H. influenzae* type b vaccines. Common bacterial infections among children 3–36 mo of age who have localizing signs include otitis media, upper respiratory tract infection, pneumonia, enteritis, urinary tract infection, osteomyelitis, and meningitis. In this age group, bacteremia is present in 11% of febrile children with pneumonia and 1.5% of febrile children with otitis media or pharyngitis.

Risk factors indicating increased probability of occult bacteremia include temperature 39℃ or greater, WBC count 15,000/ µL or greater, or an elevated absolute neutrophil count, band count, erythrocyte sedimentation rate, or C-reactive protein. The incidence of bacteremia among infants 3–36 mo of age increases as the temperature and WBC count increase. However, no combination of laboratory tests or clinical assessment is completely accurate in predicting the presence of occult bacteremia. Socioeconomic status, race, gender, and age (within the range of 3–36 mo) do not appear to affect the risk for occult bacteremia.

Without therapy, occult bacteremia may resolve spontaneously without sequelae, may persist, or may lead to localized infections, such as meningitis, pneumonia, cellulitis, or suppurative arthritis. The pattern of sequelae may be related to both host factors and the offending organism. In some children, the occult bacteremic illness may represent the early signs of serious localized infection rather than merely a transient disease state. *H. influenzae* type b bacteremia is characteristically of higher grade, as determined by quantitative blood culture techniques, and is associated with a higher risk of localized serious infection than is bacteremia due to *S. pneumoniae*. Hospitalized children with *H. influenzae* type b bacteremia often develop focal infections, such as meningitis, epiglottitis, cellulitis, or osteoarticular infection, whereas fewer than 5% of these bacteremias can be considered transient or occult. In contrast, among all patients with pneumococcal bacteremia (occult, symptomatic, or focal), spontaneous resolution occurs in 30–40%, with a higher rate of

spontaneous resolution among well-appearing children with occult pneumococcal bacteremia.

Treatment of toxic-appearing febrile children 3–36 mo of age who do not have focal signs of infection includes hospitalization and prompt institution of antimicrobial therapy after specimens of blood, urine, and CSF are obtained for culture. Meningitis in patients with occult bacteremia that develops after a lumbar puncture does not represent inoculation of bacteria by the puncture but is coincidental and represents meningeal infection that was developing before the lumbar puncture.

A retrospective review of more than 500 well-appearing febrile children discharged from an emergency department since 1987 and subsequently confirmed to be bacteremic with *S. pneumoniae* found 28% of untreated children to have persistent bacteremia or a focal infection (4% had meningitis) compared with only 5% of children who had received oral or parenteral antimicrobials when first seen (1% had meningitis). In addition, children who received antimicrobial therapy were less likely to be febrile upon return. A retrospective study of children with bacterial meningitis showed that children who received antimicrobial therapy before the diagnosis of *S. pneumoniae* meningitis was confirmed had fewer complications attributable to meningitis. These findings argue for empirical antimicrobial therapy for well-appearing children younger than 36 mo of age who have not received *H. influenzae* type b and *S. pneumoniae* conjugate vaccines who have a rectal

temperature of 39°C or greater and a WBC count of 15,000/µL or greater.

Consensus practice guidelines published in 1993 recommended that infants 3–36 mo of age who have a temperature less than 39°C and who do not appear toxic can be observed as outpatients without performing diagnostic tests or administering antimicrobial agents. For nontoxic-appearing infants with a rectal temperature of 39°C or greater, two options were suggested: (1) obtain a blood culture and give empirical antimicrobial therapy (ceftriaxone, a single dose of 50?mg/kg, not to exceed 1?g) or (2) if the WBC count is 15,000/µL or greater, obtain a blood culture and give empirical antimicrobial therapy. A third option, not offered in these guidelines, for selected infants is to obtain a blood culture and observe as outpatients without empirical antimicrobial therapy with return for re-evaluation within 24?hr. Regardless of the management option, the family should be instructed to return immediately if the child's condition deteriorates or new symptoms, such as rash, develop.

Studies of febrile infants age 3–36 mo conducted in the United States since the introduction of universal immunization of infants with *H. influenzae* type b conjugate vaccines have demonstrated that this pathogen has been virtually eliminated as a cause of occult bacteremia. In 2000, a heptavalent *S. pneumoniae* conjugate vaccine was introduced and recommended for universal administration during infancy. Based on efficacy trials, it is anticipated that there will be a significant (=90%) decrease in occult bacteremia caused by *S. pneumoniae* in vaccinated infants. Guidelines for the management of febrile children 3–36 mo of age who have received both *H. influenzae* type b and *S. pneumoniae* conjugate vaccines have yet to be established, but a stronger case for careful observation without the empirical administration of antimicrobial agents can now be made.

If *S. pneumoniae* is isolated from the blood, the child should return to the physician as soon as possible after the culture results are known. If the child appears well, is afebrile, and the physical findings remain normal, a second blood culture should be obtained if the child did not receive antimicrobial treatment at the first visit; all children should receive a total of 7–10 days of oral antimicrobial therapy. If the child appears ill and continues to have fever with no identifiable focus of infection, or if *H. influenzae* or *N. meningitidis* is present in the initial blood culture, the child should have a repeat blood culture, be evaluated for meningitis (including lumbar puncture), and either receive treatment in the hospital with appropriate antimicrobial agents or be given ceftriaxone and be managed as an outpatient. If the child develops a localized infection, therapy is directed toward the specific pathogen and the particular site.

Fever with Petechiae.

Independent of age, fever with petechiae with or without localizing signs indicates high risk for life-threatening bacterial infections such as bacteremia, sepsis, and meningitis. From 8–20% of patients with fever and petechiae have a serious bacterial infection, and 7–10% have meningococcal sepsis or meningitis (see Chapter 176). *H. influenzae* type b disease can also present with fever and petechiae (see Chapter 178). Management includes prompt hospitalization, culture of blood and CSF, and administration of appropriate parenteral antimicrobial agents.

Fever in Patients with Sickle Cell Disease.

Infection is the most common cause of death among children with sickle cell disease (see Chapter 454.1). The incidence of infection is greatest among children younger than 5 yr of age. The increased risk of infection in these children is due in part to functional asplenia and a defect in the properdin (alternate complement) pathway. Fever without localizing signs in patients with sickle cell disease is a common presentation of infection due to *S. pneumoniae* (sepsis, pneumonia, meningitis), *H. influenzae* type b (meningitis), *Staphylococcus aureus* (osteomyelitis), *Salmonella* (osteomyelitis), and *E. coli* (pyelonephritis).

The management of patients with sickle cell hemoglobinopathies requires culture of blood and, if indicated, CSF, stool, and bone, and administration of antimicrobial agents. Children who appear seriously ill, have temperatures of 40°C or greater, have WBC less than 5,000/µL or greater than 30,000/µL, or who have pulmonary infiltrates or complications of sickle cell disease or severe pain should be hospitalized. Other febrile infants with sickle cell disease can be given intramuscular ceftriaxone and cared for as outpatients after appropriate specimens have been obtained for culture. These children should be re-evaluated within 24?hr, or earlier if their condition deteriorates or new symptoms develop.

Prevention of pneumococcal sepsis is possible by instituting long-term penicillin therapy continued until adolescence (oral penicillin V, 125?mg twice daily for children younger than 5 yr of age and 250?mg orally twice daily for children 5 yr of age and older). Pneumococcal and *H. influenzae* vaccines provide some protection but do not supplant long-term antimicrobial therapy.

Hyperpyrexia.

Hyperpyrexia (temperature greater than 41°C) is uncommon and is not associated with higher rates of serious bacterial infections than temperatures of 40.0°C. Infants and children with hyperpyrexia should be carefully evaluated as for all children with fever.

FEVER OF UNKNOWN ORIGIN

The term **fever of unknown origin** (FUO) is best reserved for children with a fever documented by a health care provider and for which the cause could not be identified after 3 wk of evaluation as an outpatient or after 1 wk of evaluation in hospital. Patients with fever not meeting these criteria, and specifically those admitted to the hospital with neither an apparent site of infection nor a noninfectious diagnosis, may be considered to have **fever without localizing signs**. In most of these children, the development of additional clinical manifestations over a relatively short period confirms the infectious nature of the illness.

Etiology.

The principal causes of FUO in children, using these rigorous criteria, are infections and rheumatologic (connective tissue or autoimmune) diseases (Box 162–1).

Neoplastic disorders should also be seriously considered, although most children with malignancies do not have fever alone. The possibility of drug fever should be considered if the patient is receiving any drug.

Box 162-1. Diagnostic Considerations of Fever of Unknown Origin in Children

- Abscesses: abdominal, brain, dental, hepatic, pelvic, perinephric, rectal, subphrenic
- Diabetes insipidus (non-nephrogenic and nephrogenic)
- Infections
    - Bacteria
        - Caused by specific organism
            - Actinomycosis
            - *Bartonella henselae* (cat-scratch disease)
            - Brucellosis
            - *Campylobacter*
            - *Francisella tularensis* (Tularemia)
            - *Listeria monocytogenes* (Listeriosis)
            - Meningococcemia (chronic)
            - *Mycoplasma pneumoniae*
            - Rat-bite fever (*Streptobacillus moniliformis*; streptobacillary form of rat-bite fever)
            - Rat-bite fever (*Streptobacillus moniliformis*; streptobacillary form of rat-bite fever)
            - *Salmonella*
            - Tuberculosis
            - Yersiniosis
        - Localized infections
            - Abscesses: abdominal, brain, dental, hepatic, pelvic, perinephric, rectal, subphrenic
            - Cholangitis
            - Infective endocarditis
            - Mastoiditis
            - Osteomyelitis
            - Pneumonia
            - Pyelonephritis
            - Sinusitis
    - Spirochetes
        - *Borrelia burgdorferi* (Lyme disease)
        - Relapsing fever (*Borrelia recurrentis*)
        - Leptospirosis
        - Rat-bite fever (*Spirillum minus*; spirillary form of rat-bite fever)
        - Syphilis
    - Fungal diseases
        - Blastomycosis (extrapulmonary)
        - Coccidioidomycosis (disseminated)
        - Histoplasmosis (disseminated)
    - *Chlamydia*

- (disseminated)
  - Histoplasmosis (disseminated)
- *Chlamydia*
  - Lymphogranuloma venereum
  - Psittacosis
- Rickettsia
  - *Ehrlichia canis*
  - Q fever
  - Rocky Mountain spotted fever
  - Tick-borne typhus
- Viruses
  - Cytomegalovirus
  - Hepatitis viruses
  - HIV
    - Infectious mononucleosis (Epstein-Barr virus)
- Parasitic diseases
  - Amebiasis
  - Babesiosis
  - Giardiasis
  - Malaria
  - Toxoplasmosis
  - Trichinosis
  - Trypanosomiasis
  - Visceral larva migrans (*Toxocara*)
- Rheumatologic diseases
  - Behçet's disease
  - Juvenile dermatomyositis
  - Juvenile rheumatoid arthritis
  - Rheumatic fever

  - Juvenile dermatomyositis
  - Juvenile rheumatoid arthritis
  - Rheumatic fever

  - Systemic lupus erythematosus
- Hypersensitivity diseases
  - Drug fever
  - Hypersensitivity pneumonitis
  - Pancreatitis
  - Serum sickness
  - Weber-Christian disease
- Neoplasms
  - Atrial myxoma
  - Cholesterol granuloma
  - Hodgkin's disease
  - Inflammatory pseudotumor
  - Leukemia
  - Lymphoma
  - Neuroblastoma
  - Wilms' tumor
- Granulomatous diseases
  - Crohn's disease
  - Granulomatous hepatitis
  - Sarcoidosis
- Familial-hereditary diseases
  - Anhidrotic ectodermal dysplasia
  - Fabry's disease
  - Familial dysautonomia
  - Familial Mediterranean fever
  - Hypertriglyceridemia

Familial dysautonomia

Familial Mediterranean fever

Hypertriglyceridemia

Ichthyosis

Sickle cell crisis

Miscellaneous

Chronic active hepatitis

Diabetes insipidus (non-nephrogenic and nephrogenic)

Factitious fever

Hypothalamic-central fever

Infantile cortical hyperostosis

Inflammatory bowel disease

Kawasaki disease

Kikuchi-Fujimoto disease

Pancreatitis

Periodic fever

Poisoning

Pulmonary embolism

Thrombophlebitis

Thyrotoxicosis

Recurrent or relapsing fever

See Box 161–1

Undiagnosed fever

Persistent

Recurrent

Resolved

Drug fever is usually sustained and not associated with other symptoms. Discontinuation of the drug is associated with resolution of the fever, generally within 72?hr, although certain drugs, such as iodides, are excreted for a prolonged period with fever that may persist for as long as 1 mo after drug withdrawal.

Most fevers of unknown or unrecognized origin result from atypical presentations of common diseases. In some cases, the presentation as an FUO is characteristic of the disease, such as juvenile rheumatoid arthritis (JRA), but the definitive diagnosis can be established only after prolonged observation because initially there are no associated or specific findings on physical examination and all laboratory results are negative or normal.

In the United States, the systemic infectious diseases most commonly implicated in children with FUO (by the rigorous criteria) are salmonellosis, tuberculosis, rickettsial diseases, syphilis, Lyme disease, cat-scratch disease, atypical prolonged presentations of common viral diseases, infectious mononucleosis, cytomegalovirus (CMV) infection, viral hepatitis, coccidioidomycosis, histoplasmosis, malaria, and toxoplasmosis. Less common infectious causes of FUO include tularemia, brucellosis, leptospirosis, and rat-bite fever. AIDS alone is not usually responsible for FUO, although febrile illnesses frequently occur in patients with AIDS as a result of opportunistic infections.

JRA and systemic lupus erythematosus are the connective tissue diseases associated most frequently with FUO. Inflammatory bowel disease, rheumatic fever, and Kawasaki disease are also commonly reported as causes of FUO. If factitious fever (inoculation of pyogenic material or manipulation of the thermometer by the patient or parent) is suspected, the presence and pattern of fever should be documented in the hospital. Prolonged and continuous observation, which may include electronic surveillance, of patients is imperative. FUO lasting more than 6 mo is uncommon in children and suggests granulomatosis or autoimmune disease. Repeat interval evaluation, including history

, physical examination, and roentgenographic studies, is required.

Diagnosis.

The evaluation of FUO requires a thorough history and physical examination supplemented by a few screening laboratory tests, and additional laboratory and radiographic tests as indicated by the history or abnormalities found on examination or initial screening.

HISTORY.

The *age* of the patient is helpful in evaluating FUO. Children younger than 6 yr of age often have a respiratory or genitourinary tract infection, localized infection (abscess, osteomyelitis), JRA, or, rarely, leukemia. Adolescent patients are more likely to have tuberculosis, inflammatory bowel disease, autoimmune processes, and lymphoma, in addition to the causes of FUO found in younger children.

A history of *exposure to wild or domestic animals* should be solicited. Zoonotic infections in the United States are increasing in frequency and are often acquired from pets that are not overtly ill. Immunization of dogs against specific disorders such as leptospirosis may prevent canine disease but does not always prevent the animal from carrying and shedding leptospires, which may be transmitted to household contacts. A history of ingestion of rabbit or squirrel meat may provide a clue to the diagnosis of oropharyngeal, glandular, or typhoidal tularemia. A history of tick bite or travel to tick- or parasite-infested areas should be obtained.

Any history of *pica* should be elicited. Ingestion of dirt is a particularly important clue to infection with *Toxocara* (visceral larva migrans) or *Toxoplasma gondii* (toxoplasmosis).

A history of unusual dietary habits or travel as early as the birth of the child should be sought. Malaria, histoplasmosis, and coccidioidomycosis may re-emerge years after visiting or living in an endemic area. It is important to identify prophylactic immunizations and precautions taken by the individual against ingestion of contaminated water or food during foreign travel. Rocks, dirt, and artifacts from geographically distant regions that have been collected and brought into the home as souvenirs may serve as vectors of disease.

A *medication history* should be pursued rigorously. This should include over-the-counter preparations and topical agents, including eye drops, which may be associated with atropine-induced fever.

The *genetic background* of a patient also is important. Descendants of the Ulster Scots may have FUO because they are afflicted with nephrogenic diabetes insipidus. Familial dysautonomia (Riley-Day syndrome), a disorder in which hyperthermia is recurrent, is more frequent among Jews than other population groups. Ancestry from the Mediterranean should suggest the possibility of familial Mediterranean fever.

PHYSICAL EXAMINATION.

Sweating in a febrile child should be noted. The continuing absence of sweat in the presence of an elevated or changing body temperature suggests dehydration due to vomiting, diarrhea, or central or nephrogenic diabetes insipidus. It also should suggest anhidrotic ectodermal dysplasia, familial dysautonomia, or exposure to atropine.

A careful ophthalmic examination is important. Red, weeping eyes may be a sign of connective tissue disease, particularly polyarteritis nodosa. Palpebral conjunctivitis in a febrile patient may be a clue to measles, coxsackievirus infection, tuberculosis, infectious mononucleosis, lymphogranuloma venereum, and cat-scratch disease. In contrast, bulbar conjunctivitis in a child with FUO suggests Kawasaki disease or leptospirosis. Petechial conjunctival hemorrhages suggest infective endocarditis. Uveitis suggests sarcoidosis, JRA, systemic lupus erythematosus, Kawasaki disease, Behçet's disease, and vasculitis. Chorioretinitis suggests CMV, toxoplasmosis, and syphilis. Proptosis suggests orbital tumor, thyrotoxicosis, metastasis (neuroblastoma), orbital infection, Wegener's granulomatosis, or pseudotumor.

The ophthalmoscope should also be used to examine nailfold capillary abnormalities that are associated with connective tissue diseases such as juvenile dermatomyositis and systemic scleroderma (see Fig. 149–3). Immersion oil or lubricating jelly is placed on the skin adjacent to the nailbed, and the capillary pattern is observed with the ophthalmoscope set on +40.

FUO is sometimes due to hypothalamic dysfunction. A clue to this disorder is failure of pupillary constriction due to absence of the sphincter constrictor muscle of the eye. This muscle develops embryologically when hypothalamic structure and function also are undergoing differentiation.

Fever resulting from familial dysautonomia may be suggested by lack of tears, an absent corneal reflex, or by a smooth tongue with absence of fungiform papillae. Tenderness to tapping over the sinuses or the upper teeth suggests sinusitis. Recurrent oral candidiasis may be a clue to various disorders of the immune system.

Fever blisters are common findings in patients with pneumococcal, streptococcal, malarial, and rickettsial infection. They also are common in children with meningococcal meningitis (which usually does not present as FUO) but rarely are seen in children with meningococcemia. Fever blisters also are rarely seen with *Salmonella* or staphylococcal infections.

Hyperemia of the pharynx, with or without exudate, suggests infectious mononucleosis, CMV infection, toxoplasmosis, salmonellosis, tularemia, Kawasaki disease, or leptospirosis.

The muscles and bones should be palpated carefully. Point tenderness over a bone may suggest occult osteomyelitis or bone marrow invasion from neoplastic disease. Tenderness over the trapezius muscle may be a clue to subdiaphragmatic abscess. Generalized muscle tenderness suggests dermatomyositis, trichinosis, polyarteritis, Kawasaki disease, or mycoplasmal or arboviral infection.

Rectal examination may reveal perirectal lymphadenopathy or tenderness, which suggests a deep pelvic abscess, iliac adenitis, or pelvic osteomyelitis. A guaiac test should be obtained; occult blood loss may suggest granulomatous colitis or ulcerative colitis as the cause of FUO.

Repetitive chills and temperature spikes are common in children with septicemia (regardless of cause), particularly when associated with renal disease, liver or biliary disease, infective endocarditis, malaria, brucellosis, rat-bite fever, or a loculated collection of pus. The general activity of the patient and the presence or absence of rashes should be noted. Hyperactive deep tendon reflexes may suggest thyrotoxicosis as the cause of FUO.

LABORATORY FINDINGS.

Ordering a large number of diagnostic tests in every child with FUO according to a predetermined list may waste time and money. Alternatively, prolonged hospitalization for sequential tests may be more costly. The tempo of diagnostic

evaluation should be adjusted to the tempo of the illness; haste may be imperative in a critically ill patient, but if the illness is more chronic, the evaluation can proceed more slowly and deliberately and, usually, in an outpatient setting. If there are no clues in the patient's history or on physical examination that suggest a specific infection or area of suspicion, it is unlikely that diagnostic studies will be helpful.

A complete blood cell count with a differential WBC count and a urinalysis should be part of the initial laboratory evaluation. An absolute neutrophil count less than 5,000/μL is evidence against indolent bacterial infection other than typhoid fever. Conversely, patients with polymorphonuclear leukocytes greater than 10,000/mL or nonsegmented polymorphonuclear leukocytes greater than 500/mL have a high likelihood of having a severe bacterial infection. Direct examination of the blood smear with Giemsa or Wright stain may reveal organisms of malaria, trypanosomiasis, babesiosis, or relapsing fever.

An *erythrocyte sedimentation rate* (ESR) greater than 30?mm/hr indicates inflammation and the need for further evaluation for infectious, autoimmune, or malignant diseases. An ESR greater than 100?mm/hr suggests tuberculosis, Kawasaki disease, malignancy, or autoimmune disease. A low ESR does not eliminate the

---

possibility of infection or JRA. C-reactive protein is another acute phase reactant that becomes elevated and returns to normal more rapidly than the ESR. Although experts may prefer use of one over the other, there is no evidence that there is value in measuring both the ESR and C-reactive protein in the same patient.

Blood cultures should be obtained aerobically. Anaerobic blood cultures have an extremely low yield and should be obtained only if there are specific reasons to suspect anaerobic infection. Multiple or repeated blood cultures may be required to detect bacteremia associated with infective endocarditis, osteomyelitis, or deep-seated abscesses. Polymicrobial bacteremia suggests factitious self-induced infection or gastrointestinal (GI) pathology. The isolation of leptospires, *Francisella*, or *Yersinia* may require selective media or specific conditions not routinely used. *Urine culture* should be obtained routinely.

Tuberculin *skin testing* should be performed with intradermal placement of 5 units of purified protein derivative (PPD) that has been kept appropriately refrigerated.

Radiographic examination of the chest, sinuses, mastoids, or GI tract may be indicated by specific historical or physical findings. Radiographic evaluation of the GI tract for inflammatory bowel disease may be helpful in evaluating selected children with FUO and no other localizing signs or symptoms.

Examination of the *bone marrow* may reveal leukemia; metastatic neoplasm; mycobacterial, fungal, or parasitic diseases; and histiocytosis, hemophagocytosis, or storage diseases. If a bone marrow aspirate is performed, cultures for bacteria, mycobacteria, and fungi should be obtained.

Serologic tests may aid in the diagnosis of infectious mononucleosis, CMV infection, toxoplasmosis, salmonellosis, tularemia, brucellosis, leptospirosis, cat-scratch disease, Lyme disease, rickettsial disease, and, on some occasions, JRA. As serologic tests for more diseases become available through commercial laboratories, it is important to ascertain the sensitivity and specificity of each test before relying on these results to make a diagnosis. For example, serologic tests for Lyme disease outside of reference laboratories have been generally unreliable.

Radionuclide scans may be helpful in detecting abdominal abscesses as well as osteomyelitis, especially if the focus cannot be localized to a specific limb or multifocal disease is suspected. Gallium citrate (^{67}Ga) localizes in inflammatory tissues (leukocytes) associated with tumors or abscesses. ^{99m}Tc phosphate is useful for detecting osteomyelitis before plain roentgenograms demonstrate bone lesions. Granulocytes tagged with indium (^{111}In) or iodinated IgG may be useful in detecting localized pyogenic processes. *Echocardiograms* may demonstrate the presence of vegetation on the leaflets of heart valves, suggesting infective endocarditis. *Ultrasonography* may identify intra-abdominal abscesses of the liver, subphrenic space, pelvis, or spleen.

Total body CT or MRI permits detection of neoplasms and collections of purulent material without the use of surgical exploration or radioisotopes. CT and MRI are helpful in identifying lesions of the head, neck, chest, retroperitoneal spaces, liver, spleen, intra-abdominal and intrathoracic lymph nodes, kidneys, pelvis, and mediastinum. CT or ultrasound-guided aspiration or biopsy of suspicious lesions has reduced the need for exploratory laparotomy or thoracotomy. MRI is particularly useful for detecting osteomyelitis if there is concern about a specific limb. Diagnostic imaging can be very helpful in confirming or evaluating a suspected diagnosis but rarely leads to an unsuspected cause.

Biopsy is occasionally helpful in establishing a diagnosis of FUO. Bronchoscopy, laparoscopy, mediastinoscopy, and GI endoscopy may provide direct visualization and biopsy material when organ-specific manifestations are present.

Treatment.

Fever and infection in children are not synonymous; antimicrobial agents should not be used as antipyretics, and empirical trials of medication should generally be avoided. An exception may be the use of antituberculous treatment in critically ill children with suspected disseminated tuberculosis. Empirical trials of other antimicrobial agents may be dangerous and can obscure the diagnosis of infective endocarditis, meningitis, parameningeal infection, or osteomyelitis. Hospitalization may be required for laboratory or radiographic studies that are unavailable or impractical in an ambulatory setting, for more careful observation, or for temporary relief of parental anxiety. After a complete evaluation, antipyretics may be indicated to control fever and for symptomatic relief (see Chapter 161).

Prognosis.

Children with FUO have a better prognosis than do adults. The outcome in a child is dependent on the primary disease process, which is usually an atypical presentation

of a common childhood illness. In many cases, no diagnosis can be established and fever abates spontaneously. In as many as 25% of cases in which fever persists, the cause of the fever remains unclear, even after thorough evaluation.

Chapter 163 - Sepsis and Shock

Anne Stormorken
Keith R. Powell

The recovery of bacteria in a blood culture, or **bacteremia**, may be a transient phenomenon not associated with disease or may be the serious extension of an invasive bacterial infection originating elsewhere. Local infections, such as meningitis, osteomyelitis, endocarditis, epiglottitis, and facial cellulitis, usually follow or are concomitant with bacteremia. **Transient bacteremia** may follow instrumentation of the respiratory,

gastrointestinal, or genitourinary tracts. Bacteremia may be asymptomatic or associated with few symptoms. When bacteria are not effectively cleared by host defense mechanisms, a systemic inflammatory response is set into motion and can progress independently of the original infection. **Sepsis** is the systemic response to infection with bacteria, viruses, fungi, protozoa, or rickettsiae. Sepsis is one of the causes of the **systemic inflammatory response syndrome (SIRS)**, which has noninfectious causes as well. If not recognized and treated early, sepsis can progress to severe sepsis, **septic shock** (sepsis with hypotension), **multiple organ dysfunction syndrome (MODS)**, and death (Fig. 163–1). However, the varied clinical manifestations of sepsis may result in a broad differential diagnosis that includes many noninfectious etiologies (Box 163–1).

Etiology.

Sepsis may develop as a complication of localized community-acquired infections (see Box 163–1) or may follow colonization and local mucosal invasion by virulent pathogens (*Neisseria meningitidis, Streptococcus pneumoniae, Haemophilus influenzae* type b, *Salmonella*). Children 3 mo–3 yr of age are at risk for occult bacteremia, which occasionally progresses to sepsis (see Chapter 162).

Nosocomial infections pose a special risk to immunocompromised patients (Chapter 283). Serious gram-negative (*Escherichia coli, Pseudomonas, Acinetobacter, Klebsiella-Enterobacter, Serratia*) sepsis or fungemia occurs in neutropenic patients or intensive care patients who have become colonized with these pathogens. Sepsis caused by *Staphylococcus aureus* or coagulase-negative staphylococci may be associated with intravenous catheters (see Chapter 164) or surgical wounds. Polymicrobial sepsis also occurs in high-risk patients and is associated with central venous catheterization, gastrointestinal disease, neutropenia, and malignancy.

Figure 163-1 Progression from infection to sepsis (systemic inflammatory response syndrome [SIRS]) and its complications. (Modified from Sáez-Llorens X, McCracken GH Jr: Sepsis syndrome and septic shock in pediatrics: Current concepts of terminology, pathophysiology, and management. *J Pediatr* 1993;123: 497–508.)

Box 163-1. Differential Diagnosis of Sepsis

INFECTION

- Bacteremia or meningitis (*Streptococcus pneumoniae, Haemophilus influenzae* type b, *Neisseria meningitidis*)
- Viral illness (influenza, enteroviruses, hemorrhagic fever group, HSV, RSV, CMV, EBV)
- Encephalitis (arboviruses, enteroviruses, HSV)
- Rickettsiae (Rocky Mountain spotted fever, *Ehrlichia, Q fever*)
- Syphilis
- Vaccine reaction (pertussis, influenza, measles)
- Toxin-mediated reaction (toxic shock, staphylococcal scalded skin syndrome)

CARDIOPULMONARY

- Pneumonia (bacteria, virus, mycobacteria, fungi, allergic reaction)
- Pulmonary emboli

Pneumonia (bacteria, virus, mycobacteria, fungi, allergic reaction)

Pulmonary emboli

Congestive heart failure

Arrhythmia

Pericarditis

Myocarditis

METABOLIC-ENDOCRINE

Adrenal insufficiency (adrenogenital syndrome, corticosteroid withdrawal)

Electrolyte disturbances (hyponatremia or hypernatremia; hypocalcemia or hypercalcemia)

Diabetes insipidus

Diabetes mellitus

Inborn errors of metabolism (organic acidosis, urea cycle, carnitine deficiency)

Hypoglycemia

Reye's syndrome

GASTROINTESTINAL

Gastroenteritis with dehydration

Volvulus

Intussusception

Appendicitis

Peritonitis (spontaneous, associated with perforation or peritoneal dialysis)

Hepatitis

Hemorrhage

Hepatitis

Hemorrhage

HEMATOLOGIC

Anemia (sickle cell disease, blood loss, nutritional)

Methemoglobinemia

Splenic sequestration crisis

Leukemia or lymphoma

NEUROLOGIC

Intoxication (drugs, carbon monoxide, intentional, or accidental overdose)

Intracranial hemorrhage

Infant botulism

Trauma (child abuse, accidental)

Guillain-Barré syndrome

Myasthenia gravis

OTHER

Anaphylaxis (food, drug, insect sting)

Hemolytic-uremic syndrome

Kawasaki disease

Erythema multiforme

Hemorrhagic shock–encephalopathy syndrome

HSV, herpes simplex virus; RSV, respiratory syncytial virus; CMV, cytomegalovirus; EBV, Epstein-Barr virus.

Unusual pathogens should be considered in patients who have traveled to or been exposed to products from distant lands, or with immunocompromised states such as malignancy, T- or B-lymphocyte defects, and post-splenectomy.

Pseudobacteremia may be associated with contaminated solutions such as heparin flush solutions, intravenous infusates, albumin, cryoprecipitate, and contaminated infusion equipment. Water-associated organisms such as *Burkholderia cepacia, Pseudomonas aeruginosa*, or *Serratia* are often the contaminants.

Pathogenesis.

SIRS related to sepsis (see Fig. 163–1) results from tissue damage following the host response to bacterial products such as endotoxin from gram-negative bacteria and the lipoteichoic acid-peptidoglycan complex from gram-positive bacteria. The cardiopulmonary manifestations of gram-negative (e.g., *H. influenzae, N. meningitidis, E. coli, Pseudomonas*) sepsis can be mimicked by injection of endotoxin or tumor necrosis factor (TNF). Inhibition of TNF action by monoclonal anti-TNF antibody greatly attenuates the manifestations of septic shock in experimental models. When bacterial cell wall components are released into the bloodstream, cytokines are activated, and these in turn can lead to further physiologic derangements (Fig. 163–2). Endogenous mediators of sepsis continue to be identified and currently include TNFa; interleukin (IL) -1, -2, -4, -6, and -8; platelet-activating factor (PAF); interferon-?; eicosanoids (leukotrienes B_4 , C_4 , D_4 , E_4 ; thromboxane A_2 ; prostaglandins E_2 , I_2); granulocyte-macrophage colony-stimulating factor (GM-CSF); endothelium-derived relaxing factor; endothelin-1; complement fragments C3a and C5a; toxic oxygen radicals and proteolytic enzymes from polymorphonuclear neutrophils; adhesion molecules; platelets; transforming growth factor-s; vascular permeability factor; macrophage-derived procoagulant and inflammatory cytokine; bradykinin; thrombin; coagulation factors; fibrin; plasminogen activator inhibitors; myocardial depressant substance; s-endorphin; and heat shock proteins.

Alone or in combination, bacterial products and proinflammatory cytokines trigger physiologic responses to inhibit microbial invaders. These responses include (1) activation of the complement system; (2) activation of Hageman factor (factor XII), which then initiates the coagulation cascade; (3) adrenocorticotropic hormone and s-endorphin release; (4) stimulation of polymorphonuclear neutrophils; and (5) stimulation of the

Figure 163-2 Hypothetical pathophysiology of the septic process. ACTH, adrenocorticotropic hormone; TNF, tumor necrosis factor; IL-1, interleukin-1; PAF, platelet-activating factor; PMN, polymorphonuclear lymphocytes; IFN, interferon gamma; MODS, multiorgan dysfunction syndrome. (From Sáez-Llorens X, McCracken GH Jr: Sepsis syndrome and septic shock in pediatrics: Current concepts of terminology, pathophysiology, and management. *J Pediatr* 1993;123:497–508.)

kallikrein-kinin system (see Fig. 163–2). TNF and other inflammatory mediators increase vascular permeability, producing diffuse capillary leakage, reduced vascular tone, and at the microcirculatory level an imbalance between perfusion and increased tissue metabolic needs (Fig. 163–3).

Shock is a disruption in circulatory function leading to poor perfusion and inadequate delivery of oxygen and other nutrients to tissues (see Chapter 57.2). Shock is not diagnosed by a decrease in blood pressure because compensatory mechanisms work to maintain the blood pressure, initially through an increase in heart rate and then peripheral vasoconstriction as cardiac output decreases further. Hypotension is an ominous indicator that compensatory mechanisms are failing and cardiorespiratory arrest is imminent.

In the early phases of sepsis there is a decrease in systemic vascular resistance and a relative decline in preload, resulting in tachycardia, widened pulse pressure, and increased cardiac output. Cytokine-mediated endothelial damage leads to diffusion of intravascular fluid into tissues, compounding the degree of relative hypovolemia. Clinically, patients in the early phases of sepsis are warm and have bounding pulses with brisk capillary refill. In later phases of septic shock, patients have cool extremities with poor peripheral pulses and decreased blood pressure, reflecting myocardial dysfunction and decreased cardiac output. As tissue oxygen consumption exceeds oxygen delivery, the resultant tissue hypoxia leads to lactic acidosis.

Pulmonary function is often severely impaired. Development of adult respiratory distress syndrome (ARDS) is associated with a poor prognosis (see Chapter 58). Acute renal failure, hepatic dysfunction, pancreatitis, central nervous system dysfunction, and disseminated intravascular coagulation (DIC) can occur alone or in combination in MODS.

Figure 163-3 The hypothetical relationships between pro-inflammatory responses of the systemic inflammatory response syndrome (SIRS), compensatory anti-inflammatory syndrome (CARS), mixed anti-inflammatory syndrome (MARS), and the ensuing “CHAOS” are illustrated. (From Bone RC, Grodzin CJ, Balk RA: Sepsis: A new hypothesis for pathogenesis of the disease process. *Chest* 1997;112: 235–43.)

Clinical Manifestations.

The primary signs and symptoms of sepsis and its complications include fever, shaking chills, hyperventilation, tachycardia, hypothermia, cutaneous lesions (e.g., petechiae, ecchymoses, ecthyma gangrenosum, diffuse erythema), and changes in mental status such as confusion, agitation, anxiety, excitation, lethargy, obtundation, or coma. Secondary manifestations include hypotension, cyanosis, symmetric peripheral gangrene (purpura fulminans), oliguria or anuria, jaundice (direct hyperbilirubinemia), and signs of heart failure. There may be evidence of focal infection such as meningitis, pneumonia, arthritis, cellulitis, or pyelonephritis.

Diagnosis.

The diagnosis of septic shock includes the clinical diagnosis of shock (Chapter 57.2) with microbiologic confirmation of an infectious etiology such as a positive blood cultures or Gram stain of the serum buffy coat or petechial lesions demonstrating microorganisms. Specimens of blood, urine, and cerebrospinal fluid (CSF) as well as any exudates, abscesses, and cutaneous lesions that are present should be cultured and stained for organisms. A complete blood cell count, platelet count, prothrombin and partial thromboplastin times, fibrinogen level and D-dimer, arterial blood gas, renal and hepatic profiles, and ionized calcium should be obtained. Affected children should be admitted to an intensive care unit where invasive monitoring can be performed and central venous pressure, blood pressure, and cardiac output continuously measured (see Chapter 57).

Laboratory Findings.

Laboratory findings often include metabolic acidosis, thrombocytopenia, prolonged prothrombin and partial thromboplastin times, reduced serum fibrinogen levels and elevated fibrin split products, anemia, decreased Pa_{O_2} and increased Pa_{CO_2} , and alterations in the morphology and number of neutrophils. Elevated neutrophil and band counts (increased immature white blood cells), vacuolation of neutrophils, toxic granulations, and Döhle bodies suggest bacterial infection. Neutropenia is an ominous sign of overwhelming sepsis. Examination of the CSF may reveal neutrophils and bacteria. In the early stages of meningitis, bacteria may be detected in the CSF before development of an inflammatory response.

Treatment.

Broad-spectrum bactericidal synergistic antimicrobial agents should be promptly administered to the patient in septic shock. The choice of antimicrobial agents depends on the specific predisposing risk factors. Community-acquired disease (*N. meningitidis, S. pneumoniae, H. influenzae*) can be treated empirically with a third-generation cephalosporin (e.g., ceftriaxone or cefotaxime). Nosocomial sepsis should be treated with a third-generation cephalosporin or an extended gram-negative spectrum penicillin (e.g., mezlocillin, piperacillin-tazobactam), plus an aminoglycoside. Vancomycin should be added to the regimen if the patient has an indwelling medical device (see Chapter 165), to provide coverage for coagulase-negative staphylococci, or if meningitis is suspected to provide coverage for penicillin-resistant *S. pneumoniae*. Empirical use of amphotericin B to treat fungal infections should be considered for selected immunocompromised patients.

Supportive care in an intensive care setting is essential. Supplemental oxygen via a high-flow nonrebreathing system should be administered during initial assessment even if oxygen saturation is normal, because oxygen delivery to the tissues is compromised. Endotracheal intubation and mechanical ventilation may be necessary despite adequate ventilation or

oxygenation because of the increased work of breathing. This is especially true in infants and young children who are especially susceptible to developing respiratory failure from the tachypnea secondary to metabolic acidosis. The respiratory status in patients with a deteriorating clinical condition should be maintained and the airway controlled by elective intubation rather than waiting until urgently needed. Initially, 100% oxygen should be administered to maximize oxygen content and oxygen delivery. Positive end-expiratory pressure (PEEP) may be required to improve oxygenation because increased vascular permeability leads to the escape of fluid into the pulmonary interstitium. Hypoxemia refractory to supplemental oxygen suggests severe intrapulmonary shunting; the diagnosis of ARDS is made upon finding diffuse alveolar infiltrates on chest radiograph (see Chapter 58). Sedation and neuromuscular blockade are central to successful ventilator management in ARDS because prolonged inspiratory times and high PEEP are often required. The cardiovascular effects of PEEP should be monitored by central venous pressure and pulmonary capillary wedge pressure measurements.

Concomitant resuscitation of hemodynamic stability is necessary. If possible, two large-bore peripheral intravenous catheters should be placed and prompt administration of crystalloid begun. Although only 25% of crystalloid solutions will remain in the intravascular compartment, clinical studies do not provide evidence of the superiority of colloid to crystalloid for volume expansion. Isotonic solutions such as normal saline and lactated Ringer's solution should be given rapidly in aliquots of 20?mL/kg until perfusion, tachycardia, and hypotension resolve. Successful outcomes depend on the rapidity of infusion and may require drawing fluid into syringes and manually administering the fluid.

If the administration of 60?mL/kg of crystalloid results in no improvement, myocardial dysfunction should be considered. Many of the cytokines released during SIRS are myocardial depressants. Swan-Ganz catheter-derived data may reveal the presence of decreased myocardial contractility, poor diastolic ventricular relaxation, or abnormal systemic vascular resistance (SVR). Inotropic agents such as dopamine or epinephrine improve contractility by stimulating dopaminergic and ß-adrenergic receptors, respectively. Pressor agents such as norepinephrine restore SVR through a-adrenergic receptors. However, myocardial hyporesponsiveness to catecholamine administration during septic shock has been documented. Phosphodiesterase inhibitors (milrinone, amrinone) improve contractility, facilitate diastolic relaxation, and decrease SVR. Milrinone has been shown to improve the cardiac index by 20% in pediatric patients with septic shock. Endogenous vasopressin levels decrease during vasodilatory septic shock, and administration of low-dose vasopressin (0.02–0.04 unit/min) restores SVR. The complex etiology of myocardial dysfunction often necessitates a combination of agents.

Correction of metabolic deficiencies can also improve myocardial function. Metabolic acidosis and elevated lactate levels occur secondary to tissue hypoperfusion; however, the administration of sodium bicarbonate has not been shown to decrease morbidity or mortality in these patients. Rather, the base deficit and serum lactate are used to monitor the adequacy of resuscitation. Calcium and potassium ions are integral to the conduction and contractility of the myocardium, and their levels must be monitored and supplemented as needed. Administration of the ions is safest and most expeditious if administered via central venous access; patients must be continuously monitored.

DIC, if present, should resolve as the primary infectious disease is treated. If

bleeding occurs or the patient requires an invasive procedure, DIC should be treated with replacement of consumed coagulation factors by transfusion of fresh frozen plasma, cryoprecipitate, and platelets. Decreased serum levels of antithrombin III (AT III) and activated protein C reflect the procoagulant effect of cytokines. At present, patients with documented AT III or protein C deficiency may receive supplementation only as part of a clinical trial or as compassionate use.

Several therapies aimed at modifying overexuberant host responses have met with limited success. Such therapies include intravenous immunoglobulin, monoclonal antiendotoxin antibodies, polyclonal antiendotoxin anticore antibodies, anti-TNFa, IL-1 receptor antagonist, and granulocyte transfusions. Granulocyte transfusions are reserved for patients who have neutropenia prior to the septic episode, do not respond to antimicrobial therapy and remain persistently bacteremic. Corticosteroids are not beneficial in adults with septic shock or early ARDS; however, they may improve the clinical course during the late or fibroproliferative phase of ARDS (see Chapter 58). Stress doses of corticosteroids may be beneficial in patients with adrenal hemorrhage that is part of the Waterhouse-Friderichsen syndrome.

Prognosis.

The mortality for septic shock depends on the initial site of infection, the bacterial pathogen, the presence of MODS, and the host immune response. The mortality may be as high as 40–60% for patients with gram-negative enteric sepsis. Urosepsis has a much better prognosis than sepsis without a focus. Poor prognostic signs in meningococcal sepsis include hypotension, coma, leukopenia (<5,000 cells/μL), thrombocytopenia (<100,000/μL), low fibrinogen level (<150?mg/dL), absence of CSF pleocytosis with bacteria noted on Gram stain of the CSF, rapid appearance of petechiae (within 1?hr), and hypothermia. Furthermore, patients who survive septic shock demonstrate an improvement in cardiac indices with therapy as compared with nonsurviving patients.

Prevention.

Immunization with the conjugate *H. influenzae* type b and *S. pneumoniae* vaccines is recommended for all infants (see Chapter 282). High-risk patients should also receive the 23-valent pneumococcal vaccine, after priming with the conjugated pneumococcal vaccine, and the quadrivalent (groups A, C, Y, W-135) meningococcal vaccine at age 2 yr. Penicillin prophylaxis to prevent pneumococcal infection is recommended for patients with splenic dysfunction (e.g., sickle cell disease) and those who have had splenectomy. Prophylaxis is recommended for household and other close contacts of patients with invasive *N. meningitidis* or *H. influenzae* type b disease (see Chapters 176 and 178). Prevention of infection and sepsis in immunocompromised patients is discussed in Chapter 164 .

Chapter 164 - Infections in Immunocompromised Persons

Marian G. Michaels
Michael Green

Microbial agents are encountered throughout life. Infection and disease develop when a host's immune system is insufficient to completely protect against potential pathogens. Infections also occur in individuals with competent immune systems, usually presenting when they are naive to the microbe and have no previous immunity or because the protective barriers of the body such as the skin have been breached. However, the immunocompetent host is able to meet most infectious agents in the world with an immunologic armamentarium capable of preventing significant disease. Once an infection is established, an array of immune responses is set into action to control the disease and prevent it from reappearing. In contrast, children who are immunocompromised may not have this capability and are at increased risk for the balance being tipped in favor of the infectious agent. Depending on the level and type of immune defect, the affected child may not be able to contain the pathogen nor develop an immune response to prevent recurrence.

General practitioners are likely to see children in their practice with abnormal immune systems. Increasing numbers of children survive with primary immunodeficiencies or receive immunosuppressive therapy for treatment of malignancy, autoimmune disorders, or transplantation. For this reason, it is critical that all practitioners be comfortable with recognizing signs and symptoms of infections in these patients.

Primary immunodeficiencies are immunocompromised states that are due to genetic defects affecting one or more arms of the immune system. **Acquired, or secondary, immunodeficiencies** may result from infection, such as with human immunodeficiency virus, malignancy, or as an effect of medications. Perturbations of the mucosal and skin barriers or normal microbial flora can also be characterized as secondary immune deficiencies, leaving the host open to infections if only for a temporary period of time (Box 164–1).

The major pathogenic microbial agents among immunocompetent hosts are also the main pathogens causing infections among children with immunodeficiencies. In addition, organisms that are usually considered to be avirulent in immunocompetent hosts can be pathogenic in hosts with limited immune systems. Normal skin flora, commensal bacteria of the oral pharynx or gastrointestinal tract, environmental fungi, and common community viruses of low-level pathogenicity can cause severe, life-threatening illnesses in immunocompromised patients (Box 164–2). For this reason, close communication with the diagnostic laboratory is critical so that the laboratory does not disregard identifying normal flora and organisms normally considered to be contaminants as being unimportant.

INFECTIONS OCCURRING WITH PRIMARY IMMUNODEFICIENCIES

Abnormalities of the Phagocytic System.

Children with abnormalities of the phagocytic and neutrophil system have problems dealing with bacteria as well environmental fungi. Disease manifests as recurrent infections of the skin, mucous membranes, lungs, liver, and bones. Dysfunction of this arm of the immune

system can be due to inadequate numbers of neutrophils, abnormal movement properties, or aberrant function.

Neutropenia is defined as an absolute neutrophil count less than 1000 cells/mm^3 and can be associated with significant risk of developing severe bacterial and fungal disease, particularly when the absolute count is less than 500 cells/mm^3 . Whereas acquired neutropenia secondary to bone marrow suppression from a virus or medication is common, genetic causes of neutropenia also exist. Primary congenital neutropenia (Kostmann syndrome) most often presents during the 1st year of life with cellulitis, perirectal abscesses, or stomatitis from *Staphylococcus aureus* or *Pseudomonas aeruginosa*. Episodes of severe disease, including bacteremia or meningitis, are also possible. Even though the underlying genetic defect causing primary neutropenia remains unknown, bone marrow evaluation shows a failure of maturation of myeloid precursors. Other congenital forms of neutropenia are associated with autosomal recessive mutations, such as some forms of Kostmann syndrome and Shwachman-Diamond syndrome. Patients with Kostmann syndrome appear to have an increased risk of developing myelodysplastic syndrome and acute myelogenous leukemia. Shwachman-Diamond

syndrome is associated with a variety of other abnormalities including pancreatic insufficiency, skeletal abnormalities, and recurrent infections. Cyclic neutropenia can be an autosomal dominant disorder or sporadic mutation associated with fixed cycles of severe neutropenia between periods of normal counts. The cycles classically occur every 21 days (range, 14–36 days) with neutropenia lasting 3–6 days. Most often the disease is characterized by recurrent aphthous ulcers and stomatitis during the periods of neutropenia. However life-threatening necrotizing cellulitis and systemic disease can occur, especially with *Clostridium perfringens*. Many of the neutropenic syndromes respond to colony-stimulating factor.

Leukocyte adhesion defects are caused by defects in the s chain of integrin (CD18), which is required for the normal process of neutrophil aggregation and attachment to endothelial surfaces. In the most severe form, there is a total absence of CD18. Children with this defect may have a history of delayed cord separation and recurrent infections of the skin, oral mucosa, and genital tract. Ecthyma gangrenosum and pyoderma gangrenosum also occur. Because the defect is one of transportation and adherence to the affected area, the neutrophil count in the peripheral blood is usually extremely elevated although pus is not found at the site of infection. Survival is usually less than 10 yr without transplantation.

Chronic granulomatous disease is an inherited neutrophil dysfunction, which can be either X-linked or autosomal recessive. Neutrophils have defects in their NADPH oxidase function, rendering myeloid cells incapable of generating superoxide and thereby impairing intracellular killing. Accordingly, microbes that destroy their own hydrogen peroxide such as *S. aureus*, *Serratia marcescens*, *Burkholderia cepacia*, and *Aspergillus* cause recurrent infections in these children, especially involving the lungs, liver, and bone. Prophylaxis with trimethoprim sulfamethoxazole and recombinant human interferon-? substantially reduces the incidence of severe infections. In addition, many specialists recommend prophylaxis against *Aspergillus* with itraconazole. Patients with life-threatening infections have also been reported to benefit from aggressive treatment with white cell transfusions in addition to antimicrobial agents directed against the specific pathogen.

Defective Opsonization or Complement Deficiency.

Children with congenital asplenia, splenic dysfunction due to hemoglobinopathies such as sickle cell disease, or those who have undergone splenectomy are at risk for serious infections from bacteria. Prophylaxis with penicillin should be considered in these patients, particularly in children younger than 5 yr of age. The most common causative organisms are encapsulated bacteria including *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Salmonella*. These agents can cause sepsis, pneumonia, meningitis, and osteomyelitis. Defects in the early pathway of complement components, particularly C2 and C3, can be associated with severe infection from these bacteria. Terminal complement defects (C5, C6, C7, C8, C9) are associated with recurrent infections with *Neisseria*. Patients with complement deficiency also have an increased incidence of autoimmune disorders. Vaccines for *S. pneumoniae*, *H. influenzae* type b, and *N. meningitidis* should be given to all children with abnormalities in opsonization or complement pathways.

B-Cell Defects (Humoral Deficiencies).

Antibody deficiencies account for the majority of primary immunodeficiencies found in humans. Patients with defects in the B-cell arm of the immune system fail to produce appropriate antibody responses, with abnormalities that range from complete agammaglobulinemia to failure to produce antibody to a specific antigen or organism. Antibody deficiencies found in children with diseases such as X-linked agammaglobulinemia or common variable immunodeficiency predispose to infections with encapsulated organisms such as *S. pneumoniae* and *H. influenzae* type b. Other bacteria can also be problematic in these children (see Box 164–2). Even though most other classes of microbes (e.g. viruses, fungi) do not cause problems for these patients, some notable exceptions exist. Rotavirus can lead to chronic diarrhea, and enteroviruses can disseminate and cause a chronic meningoencephalitis syndrome. Paralytic polio has developed after immunization with live polio vaccine. In addition, protozoan infections such as giardiasis can be severe and persistent. Children with B-cell defects can develop bronchiectasis over time following chronic or recurrent infections of their lungs.

Children with antibody deficiencies are usually asymptomatic until 5–6 mo of age, when maternal passive antibody wanes. These children then begin to develop recurrent episodes of otitis media, bronchitis, pneumonia, bacteremia, and meningitis. Because many of these infections respond quickly to antibiotics, the diagnosis of antibody deficiency may be delayed. Children, especially boys, who require myringotomy tube placement before 2 yr of age because of recurrent episodes of otitis media (e.g., three or more episodes within 6 mo, or four or more episodes within 12 mo) should be considered for screening measurement of immunoglobulin levels.

The significance and impact of specific IgG subclass deficiencies is less well understood and remains controversial. Deficiencies of specific IgG subclasses were first noted in healthy adult blood

donors in whom no increased susceptibility to infections was documented. However, others have identified specific IgG deficiencies to be associated with a predisposition to recurrent bacterial sinopulmonary infection, bacteremia, meningitis, osteomyelitis, and pyoderma. Deficiency of subclass IgG_2 has been associated with poor antibody production after exposure to polysaccharide antigens, either after vaccination or infection with a polysaccharide-encapsulated organism such as *S. pneumoniae* and *H. influenzae* type b.

Selective IgA deficiency leads to a lack of production of secretory antibody at the mucosal membranes. Even though most patients will have no increased risk for infections, some will have mild to moderate disease at sites of mucosal barriers. Accordingly, recurrent sinopulmonary infection and gastrointestinal disease are the major clinical manifestations. These patients also have an increased incidence of

allergies and autoimmune disorders compared with the normal population.

Hyper-IgM syndrome is caused by a defect on the CD40 ligand on the T cell and is associated with a deficiency in the production of IgG and IgA antibody. In addition, recurrent neutropenia, hemolytic anemia, or aplastic anemia can be present. Similar to patients with agammaglobulinemia, these individuals are at risk for bacterial sinopulmonary infections, *Pneumocystis carinii* pneumonitis, and *Cryptosporidium* infection.

Replacement of antibody with intravenous immunoglobulin (IVIG) is the mainstay of treatment for most of the primary antibody deficits. The exception to this is IgA deficiency, because these patients can develop antibody against the minute amounts of IgA found in the standard IVIG preparations with an increased risk for anaphylaxis. Prophylaxis with specific antibiotic regimens is controversial and should be individualized for those patients who do not respond to immunoglobulin replacement.

T-Cell Defects (Cell-Mediated Immunity).

Children with primary cell-mediated immunodeficiencies, either isolated or more commonly in combination with B-cell defects, present early in life and are susceptible to viral, fungal, and protozoan infections. Clinical manifestations include chronic diarrhea, mucocutaneous candidiasis, pneumonia, rhinitis, and otitis media. In thymic dysplasia (DiGeorge syndrome), hypoplasia or aplasia of the thymus and parathyroid glands occurs during fetal development along with other congenital abnormalities. Hypocalcemia and cardiac anomalies are usually the presenting features of DiGeorge syndrome, which should prompt evaluation of the T-cell system. Chronic mucocutaneous candidiasis is a rare immunodeficiency associated primarily with T-cell dysfunction. These patients may lack delayed hypersensitivity to skin tests to *Candida* antigen despite having chronic infection with yeast, but do not appear to be at increased risk for systemic yeast infections. Endocrinopathies are commonly associated with chronic mucocutaneous candidiasis.

Combined B-Cell and T-Cell Defects.

Patients with defects in both the T-cell and B-cell components of the immune system may manifest a variable disease spectrum depending on the extent of the defect. Complete immunodeficiency is found with severe combined immunodeficiency syndrome (SCID), whereas partial defects can be present in such states as ataxia-telangiectasia, Wiskott-Aldrich syndrome, hyper-IgE syndrome, and X-linked immunodeficiency syndrome. Children with SCID present within the first 6 mo of life with recurrent severe infections caused by bacteria, fungi, or viruses. Failure to thrive, chronic diarrhea, mucocutaneous or systemic candidiasis, *P. carinii* pneumonitis, and cytomegalovirus (CMV) infection are common early in life. Passive maternal antibody is relatively protective against the bacterial pathogens during the first few months of life but thereafter patients are susceptible to both gram-positive and gram-negative organisms. Exposure to live virus vaccines can also lead to disseminated disease. Without bone marrow or stem cell transplantation, most children succumb to opportunistic infections within the 1st year of life.

Children with ataxia-telangiectasia develop late onset of recurrent sinopulmonary infections from both bacteria and respiratory viruses. In addition, these children experience an increased incidence of malignancies. Wiskott-Aldrich syndrome is an X-linked recessive disease associated with a reduced number of CD3 lymphocytes, moderately suppressed mitogen responses, and impaired antibody response to polysaccharide antigens. Accordingly, infections with *S. pneumoniae* or *H. influenzae* type b are common, as is *P. carinii* pneumonitis. In addition, affected boys have thrombocytopenia and eczema. Children with hyper-IgE syndrome have markedly elevated levels of IgE and present with recurrent episodes of *S. aureus* abscesses of the skin, lungs, and musculoskeletal system. While the antibody abnormality is notable, these patients also have marked eosinophilia and poor cell-mediated responses to neoantigens, and they are at increased risk for fungal infections.

INFECTIONS OCCURRING WITH ACQUIRED IMMUNODEFICIENCIES

Immunodeficiencies can be secondarily acquired as a result of infections or as a consequence of other underlying disorders such as malignancy, cystic fibrosis, diabetes mellitus, sickle cell disease, or malnutrition. Immunosuppressive medications used to prevent rejection after organ transplantation or graft-versus-host disease (GVHD) after bone marrow transplantation (BMT) leave the host vulnerable to infections. In addition, any process (burns, surgery, or the presence of indwelling catheters) that interrupts or inhibits the normal mucosal and skin barriers can be considered an acquired risk for infection.

Acquired Immunodeficiency from Infectious Agents.

Infection with HIV, the causative agent of AIDS, is the most important infectious cause of acquired immunodeficiency (see Chapter 254). If left untreated, the profound effects of HIV infection on the T-cell arm leads to susceptibility to the same types of infections as with primary T-cell immunodeficiencies.

Other viruses can lead to temporary alterations of the immune system. Transient neutropenia associated with many viruses can lead, on rare occasions, to significant disease with bacterial infections. Secondary infections can occur because of impaired immunity or disruption of the normal mucosal immunity, as exemplified by the increased risk of *S. pneumoniae* pneumonia following influenza infection and group A *Streptococcus* cellulitis and fasciitis following chickenpox.

Malignancies.

The immune systems of children with malignancies are compromised by the therapies to treat the cancer and, at times, by direct effects of the cancer itself. In addition, the presence of mucous membrane abnormalities, indwelling catheters, malnutrition, prolonged exposure to antibiotics, and frequent hospitalizations all add to the risk for infection in these children. The type, duration, and intensity of anticancer therapy remain the major risk factors for infections in these children and frequently affect more than one arm of the immune system (see Box 164–2).

Even though several arms of the immune system can be affected, the major abnormality associated with infection in children with cancer is neutropenia. The degree and duration of neutropenia have long been relied upon as accurate predictors of the risk of infection in children being treated for cancer. Patients are at particular risk for bacterial infections if the absolute neutrophil count decreases to

less than 500 cells/mm^3 . Counts greater than 500 cells/mm^3 but less than 1,000 cells/mm^3 still incur some increased risk for infection, but not nearly as great. The lack of neutrophils can lead to a loss of inflammatory response; hence, fever may be the only manifestation of infection. Accordingly, the absence of physical signs and symptoms is

not always reliable and the use of empirical antibiotics is required (Fig. 164–1).

Because patients with fever and neutropenia may only have subtle signs and symptoms of infection, the presence of fever warrants thorough physical examination with careful attention to the oropharynx, lungs, perineum and anus, skin, nailbeds, and sites along intravascular catheter sites. In addition, a comprehensive laboratory evaluation including a complete blood cell count, serum creatinine, blood urea nitrogen, and transaminases should be obtained. Blood cultures should be obtained from each port of any central venous catheter, and a peripheral venous sample should be obtained as well. Other microbiologic studies should be done if there are associated clinical symptoms: nasal aspirate for viruses in patients with upper respiratory findings; stool for rotavirus in the appropriate months and *C. difficile* in patients with diarrhea; urine culture in young children, or in older patients with symptoms of urgency, frequency, or dysuria; biopsy and culture of cutaneous lesions. Chest radiographs should be obtained in any individual with respiratory symptoms, although pulmonary infiltrates may be absent in children with severe neutropenia. Sinus films should be obtained if rhinorrhea is prolonged. Abdominal CT scans should also be considered in children with profound neutropenia and abdominal pain to evaluate for the presence of typhlitis. Biopsies for cytology, Gram stain, and culture should be considered if abnormalities are found during endoscopic procedures or if lung nodules are identified radiographically.

Before the routine institution of empirical antimicrobial therapy for fever and neutropenia, 75% of children with fever and neutropenia were ultimately found to have a documented site of infection. Currently, gram-positive cocci are the most common pathogens; however, gram-negative organisms such as *P. aeruginosa*, *E. coli*, and *Klebsiella* can cause life-threatening infection and must be considered in the empirical treatment regimen. Other gram-negative pathogens such as *Enterobacter* and

Figure 164-1 Guide to the initial management of the febrile neutropenic patient. *Recent studies suggest that cefepime or meropenem may be as effective as ceftazidime or imipenem as monotherapy. †Aminoglycoside antibiotics should be avoided if the patient is also receiving nephrotoxic, ototoxic, or neuromuscular blocking agents; has renal or severe electrolyte dysfunction; or is suspected of having meningitis (because of poor blood-brain perfusion). (Adapted from Hughes WT, Armstrong D, Bodey GP, et al: 2002 Guidelines for the use of antimicrobial agents in neutropenic patients with cancer. *Clin Infect Dis* 2002;34:730–51.)

Acinetobacter are increasing in prevalence as well. While coagulase-negative staphylococci frequently cause infections in these children in association with central venous catheters, these infections are typically indolent and a short delay in treatment will not lead to a detrimental outcome. Other gram-positive bacteria such as *S. aureus* and *S. pneumoniae* cause more fulminant disease and require prompt institution of therapy. *Viridans* streptococci are common pathogens in patients with the oral mucositis that is often associated with the use of cytarabine and selective antibiotics such as quinolones, and can present as an acute septic shock syndrome. Patients with prolonged neutropenia who have received broad antimicrobial therapy are at increased risk for opportunistic fungal infections, especially with *Candida* and *Aspergillus*.

MANAGEMENT.

Management of fever and neutropenia includes empirical antimicrobial treatment, which decreases the risks of sepsis and septic shock and the sequelae of ARDS, organ dysfunction, and death. In 2002, the Infectious Diseases Society of America updated their guidelines for the use of antimicrobial agents in neutropenic patients with cancer (see Fig. 164–1). These comprehensive guidelines provide detailed suggestions for management for both children and adults. First-line antimicrobial therapy should take into consideration the types of microbes anticipated and the local resistance patterns encountered at each institution. In addition, antibiotic choices may be limited by specific circumstances, such as the presence of drug allergy and renal or hepatic dysfunction. The empirical use of oral antibiotics has been shown to be safe in some low-risk adults who have no evidence of bacterial focus or signs of significant illness (e.g., rigors, hypotension, mental status changes) and for whom a quick recovery of the bone marrow is anticipated. However, substantive data for this approach is lacking in children and is not currently recommended. The decision to use intravenous monotherapy versus an expanded regimen of antibiotics depends on the severity of illness of the patient, history of

previous colonization with resistant organisms, and the obvious presence of catheter-related infection (see Fig. 164–1). Vancomycin should be added to empirical initial regimen if the patient has hypotension or other evidence of septic shock, an obvious catheter-related infection, or colonization with methicillin-resistant *S. aureus*, or if the patient is at high risk for viridans streptococci (severe mucositis, prior quinolone prophylaxis). Monotherapy with cefepime, ceftazidime, or a carbapenem (e.g., imipenem/cilastatin, meropenem) has been equally effective. Piperacillin-tazobactam has appropriate coverage and has also been recommended as a potential monotherapy, but it has not been adequately studied.

Regardless of the regimen chosen initially, it is critical to carefully evaluate the patient for response to therapy, development of secondary infections, or adverse effects. Patients without an identified etiology who become afebrile within the first 3–5 days of therapy and who are clinically well with absolute neutrophil counts greater than 100 cells/mm^3 can have antibiotics changed to an oral regimen (e.g., cefixime or amoxicillin/clavulanate) and should receive a minimum of 7 days of therapy. However, if symptoms persist or evolve or if neutrophils remain significantly depressed, the same intravenous regimen should be continued.

Patients without an identified etiology but with persistent fever should be reassessed after 3–5 days. Those remaining clinically well may continue on the same regimen,

although consideration should be given to discontinuing vancomycin if it was included initially. Those who remain febrile with clinical progression warrant the addition of vancomycin if not included initially and risk factors exist, as well as consideration for a change of the other antibiotics. In addition, if fever persists for more than 5 days, the addition of an antifungal agent such as fluconazole or amphotericin B is generally warranted. Because not all fevers are due to bacterial or fungal etiologies, patients with persistent fever without an identified cause and without complications may have therapy discontinued 4–5 days after the neutrophil count is greater than 500 cells/mm^3 . Clinically stable patients without an identified etiology but with persistent neutropenia after 2 wk of therapy can be considered for discontinuation of antibiotics if continued close observation can be assured.

The use of antiviral agents in fever and neutropenia is not warranted without specific evidence of viral disease. Active herpes simplex or varicella-zoster lesions merit treatment to decrease the time of healing; even if they are not the source of fever they are potential portals of entry for bacteria and fungi. CMV is rarely a cause of fever in children with cancer and neutropenia. If CMV infection is strongly suspected, ganciclovir, foscarnet, or cidofovir may be considered, although ganciclovir can cause bone marrow suppression and foscarnet and cidofovir can be nephrotoxic (see Chapter 234). If influenza is identified, specific treatment with zanamivir, oseltamivir, rimantadine, or amantadine should be administered (see Chapter 237).

The use of hematopoietic growth factors shortens the duration of neutropenia but has not been proven to reduce morbidity or mortality. Accordingly, the 2002 recommendations from the Infectious Diseases Society of America do not endorse the routine use of hematopoietic growth factors in patients with uncomplicated fever and neutropenia.

Infections occur in children with cancer even without neutropenia. Most often these organisms are viral in etiology. However, *P. carinii* can cause pneumonitis regardless of the neutrophil count. Prophylaxis with trimethoprim-sulfamethoxazole against *P. carinii* is an effective preventive strategy and should be provided to all children undergoing active treatment for malignancy (see Chapter 267). Environmental fungi such as *Cryptococcus*, *Histoplasma*, and *Coccidioides* can also cause disease. *Toxoplasma gondii* is an uncommon but occasional pathogen in children with cancer. Infections encountered in healthy children (e.g., *S. pneumoniae*, group A *Streptococcus*) can cause disease in children with cancer regardless of the granulocyte count.

Transplantation.

Transplantation of bone marrow, stem cells, and organs including heart, liver, kidney, lungs, pancreas, and intestines is increasingly accepted as therapy for a variety of disorders. Children with transplants are at risk for infections caused by many of the same microbial agents that cause disease in children with primary immunodeficiencies. Although the type and timing of infections after transplantation are in general similar among all recipients of these procedures, some differences exist between patients depending on the type of transplantation performed, the type and amount of immunosuppression given, and the child's previous immunity to specific pathogens.

BONE MARROW AND STEM CELL TRANSPLANTATION.

Infections following BMT and stem cell transplantation (SCT) can be classified as occurring during the pretransplantation period, pre-engraftment period (0–30 days after transplantation), postengraftment period (30–100 days), or late post-transplantation (>100 days). Specific defects in host defenses predisposing to infection and their underlying causes vary within each of these time periods (Table 164–1). Neutropenia, abnormalities in cell-mediated immunity, and impaired humoral immune function predictably occur during specific time periods following transplantation, whereas abnormal anatomic barriers, due to the presence of indwelling catheters as well as mucositis secondary to radiation or chemotherapy, create defects in host defenses that may be present during any of the time periods following transplantation.

Pretransplantation Period. Children come to BMT and SCT with a heterogenous history of underlying diseases, chemotherapy exposure, degree of immunosuppression, and previous infections. As many as 12% of all infections among adult BMT recipients are reported to occur during the pretransplantation time period. The majority of infections that occur during the pretransplantation time period are caused by aerobic gram-negative bacilli and are manifest as local infections of the skin, soft tissue, and urinary tract. Importantly, the development of infection during this time period does not either delay engraftment nor alter the success of engraftment.

Pre-engraftment Period. Bacterial infections predominate in the pre-engraftment period (0–30 days). Bacteremia is the most common documented infection and occurs in as many as 50% of all BMT recipients during the first 30 days following transplantation. Bacteremia is typically secondary to either mucositis or the presence of an indwelling catheter but may be associated with pneumonia. Similarly, more than 40% of children undergoing SCT experienced at least one infection in the pre-engraftment period. Gram-positive cocci, gram-negative bacilli, yeast and, less commonly, other fungi all cause infection during this period. *Aspergillus* has been identified in 4–20% of BMT recipients, most often being diagnosed after the 3rd week of neutropenia. Infections with the emerging fungal pathogens *Fusarium* and *Pseudallescheria boydii* are associated with the prolonged neutropenia observed during the pre-engraftment period.

Viral infections also occur during the pre-engraftment period. Among adults, reactivation of herpes simplex virus is the most common viral disease observed but this is a less frequent occurrence among children, which is likely related to absence of the virus in the recipient before BMT or SCT. A history of herpes simplex infection or seropositivity indicates the need for prophylaxis. Nosocomial exposure to community-acquired viral pathogens (e.g., respiratory syncytial virus [RSV], influenza, adenovirus, rotavirus) represents another important source of infection during this time period. There is growing evidence that community-acquired viruses cause both morbidity and mortality for BMT recipients during this time period. Adenovirus is a particularly important viral pathogen that may present early, although it typically presents after engraftment.

Postengraftment Period. The predominant defect in host defenses in the

postengraftment period is altered cell-mediated immunity. Accordingly, organisms historically categorized as

TABLE 164-1 -- **Host Defense Defects and Common Pathogens by Time After Bone Marrow Transplantation and Stem Cell Transplantation**

Time Period	Host Defense Defects	Causes	Common Pathogens
Pretransplant	Neutropenia	Underlying disease	Aerobic gram-negative bacilli
	Abnormal anatomic barriers	Prior chemotherapy	
Pre-engraftment	Neutropenia	Chemotherapy	Aerobic gram-positive cocci
	Abnormal anatomic barriers	Radiation	Aerobic gram-negative bacilli
		Indwelling catheters	*Candida*
			Aspergillus
			Herpes simplex virus (in previously infected patients)
			Community-acquired viral pathogens
Postengraftment	Abnormal cell-mediated immunity	Chemotherapy	Gram-positive cocci
	Abnormal anatomic barriers	Immunosuppressive medications	Aerobic gram-negative bacilli
		Radiation	Cytomegalovirus
		Indwelling catheters	Adenoviruses
		Unrelated cord blood donor	Community-acquired viral pathogens
			Pneumocystis carinii
Late post-transplant	Delayed recovery of immune function (cell-mediated, humoral, and abnormal anatomic barriers	Time required to develop donor-related immune function	Varicella-zoster virus
			Streptococcus pneumoniae
		Graft-vs-host disease	

“opportunistic pathogens” predominate during this time period. The risk is especially accentuated 50–100 days after transplant when host immunity is lost and donor immunity is not yet established. *P. carinii* pneumonia presents during this time period if patients are not maintained on appropriate prophylaxis. Reactivation of *T. gondii*, a rare cause of disease in BMT recipients, may also present after engraftment. Hepatosplenic candidiasis frequently presents during the postengraftment period, although seeding likely occurred during the neutropenic phase.

CMV is one of the most important causes of morbidity and mortality among BMT and SCT recipients. Unlike patients undergoing solid organ transplantation, BMT and SCT recipients developing either a primary infection or reactivation of their own latent virus may develop severe CMV disease. Adenovirus is another important viral pathogen, having been recovered from up to 5% of adult BMT and pediatric SCT recipients and causing invasive disease in approximately 20% of cases. Children receiving matched unrelated donors or unrelated cord blood cell transplants have as high as 14% incidence of adenovirus infection during this early postengraftment period. Infections with other community-acquired pathogens have been associated with excess morbidity and mortality during this time period, similar to the pre-engraftment time.

Late Post-transplantation. Infection is unusual after 100 days in the absence of chronic graft-versus-host disease. The presence of chronic graft-versus-host disease significantly affects anatomic barriers and is associated with defects in humoral, splenic, and cell-mediated immune function (see Chapter 127). Viral infections, primarily reactivation of varicella-zoster virus, are responsible for more than 40% of infections during this time period. However, bacterial infections, particularly of the upper and lower respiratory tract, account for approximately one third of infections. These may be associated with deficiencies in immunoglobulin production or synthesis, especially IgG_2 . Fungal infections account for less than 20% of confirmed infections during the late post-transplant time period.

SOLID ORGAN TRANSPLANTATION.

Factors predisposing to infection after organ transplantation include those that either existed before transplantation or those that are secondary to intraoperative or post-transplant therapies (Box 164–3). Some of these additional risks cannot be prevented, and some risks acquired during or after the operation may be dependent on decisions or actions of members of the transplant team. Currently, the necessity for powerful immunosuppressive agents is the major factor predisposing to infection following transplantation. Despite efforts to develop optimal immunosuppressive regimens to prevent or treat rejection with minimal impairment of immunity,

Box 164-3. Risk Factors for Infections Following Solid Organ Transplantation in Children

PRETRANSPLANT FACTORS

- Age of patient
- Underlying disease, malnutrition
- Specific organ transplanted
- Previous exposures to infectious agents
- Previous immunizations

INTRAOPERATIVE FACTORS

- Duration of transplant surgery
- Exposure to blood products
- Technical problems
- Organisms transmitted with donor organ

POST-TRANSPLANT FACTORS

- Immunosuppression
  - Induction immunosuppression
  - Maintenance immunosuppression
  - Augmented treatment for rejection
- Indwelling catheters
- Nosocomial exposures
- Community exposures

all current regimens interfere with the ability of the immune system to fight infection. The majority of these immunosuppressive agents are aimed primarily at controlling cell-mediated immunity; however, regimens may impair many other aspects of the transplant recipient's immune system.

Timing.

The timing of specific types of infections is generally predictable, regardless of which organ is transplanted (Table 164–2). Infectious complications typically develop in one of three time intervals: early (0–30 days after transplantation), intermediate (30–180 days, or 1–6 mo), and late (>180 days, or >6 mo); most infections develop in the first 180 days after transplantation. Early infections usually result as either a complication of the transplant surgery itself or the presence of indwelling catheters. Infections during the intermediate time period typically result as a complication of the immunosuppression, which tends to be at its greatest intensity during the first 6 mo following transplantation. This is the time period of greatest risk for infections due to opportunistic pathogens such as CMV and *P. carinii*. Anatomic abnormalities, such as bronchial stenosis and biliary stenosis, developing as a consequence of the transplant surgery can also predispose to recurrent infection that present in this time period. Infections developing late after transplantation typically result as a consequence of uncorrected anatomic abnormalities, chronic rejection or exposure to

TABLE 164-2 -- Timing of Infectious Complications Following Solid Organ Transplantation

Early Period (0–30 days)	Middle Period (1– 6 mo)	Late Period (>6 mo)
Bacterial Infections	Viral Infections	Viral Infections
Gram-negative enteric bacilli	Cytomegalovirus	Epstein-Barr virus
Small bowel, liver, neonatal heart	All transplant types	All transplant types, but less risk than middle period
Pseudomonas, Burkholderia,	Seronegative recipient of seropositive donor	Varicella-zoster virus
Stenotrophomonas, Alcaligenes	Epstein-Barr virus	All transplant types
Cystic fibrosis lung	All transplant types (small bowel highest risk group)	Community-acquired viral infections
Gram-positive organisms	Seronegative recipient	All transplant types
All transplant types	Varicella-zoster virus	Bacterial Infections

Fungal infections	All transplant types	*Pseudomonas, Burkholderia, Stenotrophomonas, Alcaligenes*
All transplant types	Opportunistic infections	Cystic fibrosis lung
Viral infections	*Pneumocystis carinii*	Lung recipients with chronic rejection
Herpes simplex virus	All transplant types	Gram-negative bacillary bacteremia
All transplant types	*Toxoplasma gondii*	Small bowel
Nosocomial respiratory viruses	Seronegative recipient of cardiac transplant from a seropositive donor	Fungal infections
All transplant types		*Aspergillus*
	Bacterial infections	Lung transplants with chronic rejection
	Pseudomonas, Burkholderia, Stenotrophomonas, Alcaligenes	
	Cystic fibrosis lung	
	Gram-negative enteric bacilli	
	Small bowel	

Adapted from Green M, Michaels MG: Infections in solid organ transplant recipients. In Long SS, Pickering L, Prober C, editors: Principles and Practice of Pediatric Infectious Disease. NewYork, Churchill Livingstone, 1997.

community-acquired pathogens. Acquisition of infection due to community-acquired pathogens, such as RSV, may result in severe infection secondary to the immunocompromised state of the transplant recipient during the early and intermediate periods. Compared to the earlier periods, community-acquired infections in the late period are usually benign because levels of immunosuppression are typically maintained at significantly lower levels. However, certain pathogens, such as varicella-zoster virus (VZV) and Epstein-Barr virus (EBV), may be associated with severe disease even at this late time period.

Bacterial and Fungal Infections. Although there are important graft-specific considerations for bacterial and fungal infections following transplantation, some principles are generally applicable to all transplant recipients. Bacterial and fungal infections following transplantations are usually a direct consequence of the surgery, a breach in an anatomic barrier, presence of foreign body, or an abnormal anatomic narrowing or obstruction. With the exception of infections related to the use of indwelling catheters, sites of bacterial infection tend to occur at or near the transplanted organ. Infections following abdominal transplantation (e.g., liver, intestine, or renal) usually occur in the abdomen or at the surgical wound. The pathogens are typically enteric gram-negative bacteria, *Enterococcus*, and occasionally *Candida*. Infections following thoracic transplantation (e.g., heart, lung) usually occur in the lower respiratory tract or at the surgical wound. Pathogens associated with these infections include *S. aureus* and gram-negative bacteria. Patients undergoing lung transplantation for cystic fibrosis experience a particularly high rate of infectious complications, because they are frequently colonized with *Pseudomonas* or *Aspergillus* before transplantation. Even though the infected cystic lungs are removed, the sinuses and upper airways remain colonized with these same pathogens and subsequent reinfection of the transplanted lungs is not infrequent. Children receiving organ transplants have frequently been hospitalized for long periods and have received many antibiotics, thus recovery of bacteria with multiple antibiotic resistance is common after all types of organ transplantation. Infections due to *Aspergillus* are less common but occur after all types of organ transplantation and are associated with high rates of morbidity and mortality.

Viral Infections. Viral pathogens, especially herpesviruses, are a major source of morbidity and mortality following solid organ transplantation. The patterns of disease associated with individual viral pathogens generally are similar among all organ transplant recipients. However, the frequency, mode of presentation, and severity differ according to type of organ transplanted and pretransplant serologic status of the recipient.

Viral pathogens can be categorized as **donor-associated viruses**, such as CMV and EBV, or as community-acquired viruses. For CMV and EBV, primary infection occurring after transplantation is associated with the greatest degree of morbidity and mortality. The highest risk is in a naive host who receives an organ from a donor who previously was infected with one of these viruses. This “mismatched state” is a frequent cause of severe disease. However, even if the donor is negative for CMV and EBV, these infections can be acquired from a close contact or via blood products. Reactivation of a latent strain within the host, or superinfection with a new strain, tends to result in milder illness unless the patient is greatly immunosuppressed, which may occur in the setting of treatment of significant rejection. CMV is the most commonly recognized transplant viral pathogen and remains a major cause of disease after solid organ transplantation. Disease can range from a syndrome of fatigue and fever to disseminated disease that most often affects the liver, lungs, and gastrointestinal tract. Infection due to EBV is increasingly recognized as another important complication of solid organ transplantation ranging from a mild mononucleosis syndrome to disseminated post-transplant lymphoproliferative disorder (PTLD). PTLD is more common among children than adults because primary EBV infection in the immunosuppressed host is more likely to lead to uncontrolled proliferative disorders, including post-transplant lymphoma. Other donor-associated viral pathogens include hepatitis B virus, hepatitis C virus, HIV, and occasionally adenoviruses.

Community-acquired viruses, including respiratory viruses (e.g., RSV, influenza, and parainfluenza) and enteric viruses (e.g., enteroviruses, rotavirus), may cause important disease in children following organ transplantation. In general, risk factors for more severe infection include young age, acquisition of infection early after transplantation, and augmented immune suppression. Infection in the absence of these risk factors typically results in a clinical illness that is comparable to that seen in immunocompetent children.

Opportunistic Pathogens. Children undergoing solid-organ transplantation are also

at risk for symptomatic infections from pathogens that do not usually cause clinical disease in

immunocompetent hosts. Even though most frequently recognized in the intermediate time period, these infections can also occur late in patients requiring prolonged and high levels of immunosuppression. *P. carinii* is a well recognized cause of pneumonia following solid organ transplantation, although routine prophylaxis has essentially eliminated this problem. *T. gondii* may complicate cardiac transplantations, because of tropism of the organism for cardiac muscle and risk for donor transmission, and rarely may complicate renal and liver transplants.

PREVENTION OF INFECTION IN IMMUNOCOMPROMISED HOSTS

Infections cannot be completely prevented in children who have defects in one or more arms of their immune system, although some measures can decrease the risks for infection. For example, replacement immunoglobulin is a benefit to children with primary B-cell deficiencies, and IFN-? and trimethoprim-sulfamethoxazole reduce the number of infections occurring in children with chronic granulomatous disease. Likewise, children with depressed cellular immunity from primary diseases, AIDS, or use of immunosuppressive medications benefit from prophylaxis against *P. carinii*. Immunizations prevent many infections that would be a problem for any host but particularly for children with compromised immune systems. Immunizations should ideally be administered before any treatment that would compromise the child's immune system; however, this is not always possible such as with primary immune defects or in children who require transplants early in life.

While immunodeficient children represent a heterogeneic group, some principles of prevention are generally applicable. Inactivated vaccines do not lead to an increased risk of adverse effects, although their efficacy may be reduced due to an impaired immune response. Live, attenuated virus vaccinations can cause disease in some children with immunologic defects, and therefore alternative immunizations should be used whenever possible, such as the use of inactivated polio vaccine rather than live virus oral polio vaccine. In general, live virus vaccines should not be used in children with primary T-cell abnormalities. However, in some instances in which wild type viral infection can be severe, immunizations, even with live virus vaccine, are warranted. For example, children with HIV infection and CD4 percentage greater than 15% should receive measles vaccination, and they should receive varicella vaccine if CD4 percentage is greater than 25%. Some vaccines should be given to children with immunodeficiencies in addition to routine vaccinations. For example, the meningococcal vaccine and both the polysaccharide pneumococcal vaccine as well as the conjugate pneumococcal vaccine should be given to children with splenic dysfunction or complement deficiency. Influenza vaccination should be strongly considered for immunocompromised children as well as all household contacts, to minimize risk of transmission to the immunocompromised child.

Chapter 165 - Infection Associated with Medical Devices

Patricia M. Flynn
Fred F. Barrett

Despite the therapeutic successes and convenience of the many synthetic devices used in pediatric patients, infectious complications are problematic. The pathogenesis of device-related infection is not completely defined, but many factors are important, including the susceptibility of the host, the composition of the device, the ability of microorganisms to adhere to the device itself or to the biofilm that quickly forms on it, and environmental factors that include the insertion technique and maintenance of the device.

Intravascular Access Devices.

Intravascular access devices range from short stainless steel needles to multilumen implantable synthetic plastic catheters that are expected to remain in use for years. Infectious complications include localized infections (exit site infection, tunnel tract infection, suppurative phlebitis) and systemic infections (catheter-related bacteremia and fungemia). The pathogenesis is most often related to local contamination and subsequent colonization of the catheter rather than primary bacteremia or secondary bacteremia from another focus seeding the intravascular device. Infection with the microbial skin flora at the insertion site may extend along the external surface of the catheter. This route of infection is most common in intravascular catheters in place for less than 30 days. Organisms may also gain access to the intraluminal portion of the catheter through improper handling of the catheter hub or contaminated infusate. This route of infection is thought to be more prevalent in catheters in place greater than 30 days. Gram-positive cocci predominate in both categories; more than half are caused by coagulase-negative staphylococci. Gram-negative enteric bacteria are isolated in approximately 20–30% of episodes, and fungi account for 5–10%.

The clinical manifestations of local infection include erythema, tenderness, and purulent discharge at the exit site or along the subcutaneous tunnel tract of the catheter. Catheter-related sepsis may also present as fever without an identifiable focus.

The diagnosis of localized infection is established clinically. A Gram stain and culture of exit site drainage should be performed and may help elucidate the microbiologic cause. The diagnosis of catheter-related bacteremia is confirmed by performing quantitative blood cultures simultaneously from the catheter and the peripheral vein. Evidence of catheter-related bacteremia or fungemia is more than 4–10 times the number of organisms isolated from blood obtained via the catheter as compared to blood obtained via a peripheral vein. If quantitative blood cultures are not available, a catheter blood culture that becomes positive more than 2?hr before a peripheral culture, with equal amounts of blood using a radiometric detection system, may also be used for diagnosis. Catheter-related sepsis can also be diagnosed by isolation of the same organism from the blood and the catheter

tip. This method, however, requires catheter removal and is not optimal for patients with long-term devices.

Short-term peripheral catheters are most commonly used in pediatric patients, and infectious complications occur infrequently. The rate of peripheral catheter-related bacteremia is less than 0.15%. Patient age younger than 1 yr, duration of use more than 144?hr, and selected (e.g., total parenteral nutrition, lipid) infusates are associated with increased risk of catheter-related infection.

Central venous catheters (CVCs) are widely used in both adults and pediatric patients and are responsible for the majority of catheter-related infections. They are commonly used in critically ill patients, including neonates, who often have many risk factors for the development of nosocomial infection. Patients who are in an intensive care unit and who have a CVC in place have a fivefold greater risk of developing a nosocomial bloodstream infection than those without a CVC. The means for optimal maintenance of these catheters remains controversial. Although prevalence of infection increases with prolonged duration of catheter use, routine replacement of a CVC results in significant morbidity. Current guidelines suggest placement with full barrier precautions either via a new site or exchange of the catheter over a guide wire, but without a policy for routine replacement.

The use of peripherally inserted central catheters (PICCs), which are inserted into a peripheral vein with the distal end in a central vein, has increased in pediatric patients. Published experience with these devices in children is scanty, but studies in adults document a life span of approximately 3 mo and infection rates of 1.9 episodes/1,000 catheter-days, significantly lower than for CVCs.

When prolonged intravenous access is required, a cuffed silicone rubber (Silastic) catheter may be inserted into the right atrium through the subclavian, cephalic, or jugular vein. The extravascular segment of the catheter passes through a subcutaneous tunnel before exiting the skin, usually on the superior aspect of the chest (Broviac or Hickman catheters). Totally implanted devices consist of a reservoir or port placed in a subcutaneous pocket with a self-sealing silicone septum at the distal end that permits repeated percutaneous needle insertions for administration of drugs. The use of central venous devices has improved the quality of life of high-risk patients but has also increased the risk of various infections. The incidence of local (exit site, tunnel, pocket) infection is 0.2–2.8/1,000 catheter-days.

The incidence of Broviac or Hickman catheter-associated sepsis is 0.5–6.8/1,000 catheter days, whereas that for implantable devices is 0.3–1.8/1,000 catheter-days. The risk of catheter infection is increased among premature infants, young children, and those receiving total parenteral nutrition.

If either localized or systemic catheter-related infection is diagnosed in a short-term peripheral catheter or CVC, the device should be removed. Antibiotics should be administered in cases of systemic infection, with the exception of uncomplicated coagulase-negative staphylococcal bacteremia in normal hosts, for which catheter removal is sufficient.

For infections associated with long-term vascular access devices (Hickman, Broviac, totally implantable devices), antibiotic treatment is successful for most systemic bacterial infections without removal of the device. Antibiotic therapy should be directed to the isolated pathogen and given for a total of 10–14 days. Until identification and susceptibility testing are available, empirical therapy with a third-generation cephalosporin or aminoglycoside plus vancomycin is indicated. **“Antibiotic lock” or “dwell” therapy**, with administration of solutions of high concentrations of antibiotics that remain in the catheter for up to 24?hr, may improve outcome. If blood cultures remain positive after 72?hr of appropriate therapy, as confirmed by susceptibility testing, or if a patient deteriorates clinically, the device should be removed. Most experts advocate removal of the device as well as therapy with systemic antifungals in cases of catheter-related fungemia. Exit-site infections usually respond to local care or systemic antibiotics, but tunnel tract infections require removal of the catheter in approximately two thirds of patients.

PREVENTION OF INFECTION.

Prevention of infections of long-term vascular access devices includes placement using meticulous surgical aseptic technique in an operating room–like environment, routine use of antibacterial ointment, avoidance of occlusive or semipermeable dressings, avoidance of bathing or swimming, and careful catheter care. The use of CVCs impregnated with antibiotics may be a future means to prevent catheter-related infection.

Cerebrospinal Fluid Shunts.

Cerebrospinal fluid (CSF) shunting is required for the treatment of many children with hydrocephalus. The usual procedure uses a silicone rubber device with a proximal portion inserted into the ventricle, a unidirectional valve, and a distant segment that diverts the CSF from the ventricles to either the peritoneal cavity (ventriculoperitoneal, or VP shunt) or right atrium (ventriculoatrial, or VA shunt). The incidence of shunt infection ranges from 1–20%, with an average of 10%. The highest rates are reported in young infants. Most infections are a result of intraoperative contamination of the surgical wound by skin flora. Accordingly, coagulase-negative staphylococci are isolated in more than half of the cases. *Staphylococcus aureus* is isolated in approximately 20% and gram-negative bacilli in 15%.

Four distinct clinical syndromes have been described: colonization of the shunt, infection associated with wound infection, distal infection with peritonitis, and infection associated with meningitis.

The most common type of infection is “colonization” of the shunt with symptoms that reflect shunt malfunction as opposed to shunt infection per se. Symptoms associated with colonized VP shunts include lethargy, headache, vomiting, and a full fontanel. Low-grade fever is common. Symptoms usually occur within months of the surgical procedure. Colonization of a VA shunt results in more severe systemic symptoms and often without specific symptoms of shunt malfunction. Septic pulmonary emboli, pulmonary hypertension, and infective endocarditis are frequently reported complications of VA shunt colonization. Chronic VA shunt colonization may cause hypocomplementemic glomerulonephritis due to antigen-antibody complex deposition in the glomeruli, which is commonly called **shunt nephritis**; clinical findings include hypertension, microscopic hematuria, elevated blood urea nitrogen (BUN) and serum creatinine levels, and anemia. With shunt colonization, CSF obtained from either lumbar or ventricular puncture is often sterile, and the infecting organism is isolated only from the shunt reservoir. Because of this, it is unusual to observe signs of ventriculitis, and CSF findings are only minimally abnormal. Blood culture results are usually negative in cases of VP colonization but positive in VA shunt colonization.

Wound infection presents with obvious infection or dehiscence along the shunt tract and most often occurs within days to weeks of the surgical procedure. *S. aureus* is the most common isolate. In addition to the physical findings, fever is common, and signs of shunt malfunction eventually ensue in most cases.

Distal infection of VP shunts with peritonitis presents with abdominal symptoms, usually without evidence of shunt malfunction. The pathogenesis is likely related to perforation of bowel at the time of VP shunt placement or translocation of bacteria across the bowel wall. Thus, gram-negative isolates predominate and mixed infection is common. The infecting organisms are often isolated from only the distal portion of the shunt.

The usual meningeal pathogens, *Streptococcus pneumoniae, Neisseria meningitidis*, and *Haemophilus influenzae* type b, can also

---

cause bacterial meningitis in patients with shunts in place. The clinical presentation is similar to that for acute bacterial meningitis (see Chapter 594).

Treatment of shunt colonization and distal infection with peritonitis includes the use of antibiotics against the specific organisms isolated and, in most situations, removal of the shunt. Intrashunt antibiotics are indicated because of the poor penetration of most antibiotics into the CNS across uninflamed meninges. If the isolate is susceptible, a parenteral antistaphylococcal penicillin plus intrashunt vancomycin is the treatment of choice. If the organism is resistant to the penicillins, systemic and intrashunt vancomycin is recommended. In cases of gram-negative infections, a combination of a third-generation cephalosporin and intrashunt aminoglycoside is optimal. When using intrashunt antibiotics, monitoring of CSF levels is necessary to avoid toxicity. The best treatment success occurs with initial systemic and intrashunt

antibiotics in combination with exteriorization of the distal end of the shunt. After CSF from the reservoir has remained sterile for 48?hr, shunt replacement on the opposite side can be performed. Partial shunt revision with antibiotic therapy or antibiotic therapy alone has been successful in some series, but the relapse rate is higher. When wound infection is diagnosed, the shunt most always needs to be removed. To allow for continued ventricular drainage, a temporary catheter is often placed, with replacement of a new shunt on the opposite side after the wound infection has healed. Only systemic antibiotics are necessary for treatment of bacterial meningitis in patients with a shunt in place; the shunt itself does not need to be removed.

PREVENTION OF INFECTION.

Prevention of shunt infection includes meticulous cutaneous preparation and surgical technique. Systemic and intraventricular antibiotics and soaking the shunt tubing in antibiotics have been used to reduce the incidence of infection, with varying success. A meta-analysis of 12 clinical trials using various antimicrobial regimens involving 1,359 randomized patients showed that perioperative use of an antimicrobial agent in CSF shunt placement reduced the risk for infection, although only 1 of the 12 studies individually revealed an effect.

Urethral Catheters.

Urinary catheters are a frequent cause of nosocomial infection, with about 14 infections/1,000 admissions. Like other devices, microorganisms adhere to the catheter surface and establish a biofilm that allows proliferation. The physical presence of the catheter reduces the normal host defenses by preventing complete emptying of the bladder, thus providing a medium for growth, distending the urethra, and blocking periurethral glands. Almost all patients catheterized for more than 30 days develop bacteriuria. The urinary tract is considered infected if specimens of urine obtained directly from an indwelling catheter harbor greater than or equal to 100 colony-forming units/mL. Gram-negative bacilli and *Enterococcus* are the predominant organisms isolated in catheter-related urinary tract infection; coagulase-negative staphylococci are implicated in about 15%. Symptomatic urinary tract infections should be treated with antibiotics and catheter removal. Asymptomatic infections can usually be managed with catheter removal alone.

PREVENTION OF INFECTION.

All urinary catheters introduce risk for infection, and their casual use should be avoided. When they are in place, their duration of use should be minimized. Technologic advances have led to development of silver-or antibiotic-impregnated urinary catheters that are associated with lower rates of infection. Prophylactic antibiotics do not reduce the infection rates for long-term indwelling urethral catheters.

Peritoneal Dialysis Catheters.

During the 1st yr of peritoneal dialysis for end-stage renal disease, 65% of children will have one or more episodes of peritonitis. Bacterial entry comes from luminal or periluminal contamination of the catheter or by translocation across the intestinal wall. Hematogenous infection is rare. Infections can be localized at the exit site, associated with peritonitis, or both. Organisms responsible for peritonitis include coagulase-negative staphylococci (30–40%), *S. aureus* (10–20%), streptococci (10–15%), *Escherichia coli* (5–10%), *Pseudomonas* (5–10%), other gram-negative bacteria (5–15%), *Enterococcus* (3–6%), and fungi (2–10%). *S. aureus* is more common in localized exit or tunnel tract infections (42%). Most infectious episodes are due to a patient's own flora, and carriers of *S. aureus* have been shown to have increased rates of infection as compared with noncarriers.

The clinical manifestations of peritonitis may be subtle and include low-grade fever, mild abdominal pain, and tenderness. Cloudy peritoneal dialysis fluid may be the first and predominant sign. With peritonitis, the peritoneal fluid cell count is usually greater than 100 white blood cells/µL. When peritonitis is suspected, the effluent dialysate should be submitted for cell count, Gram stain (which is positive in up to 40% if peritonitis is present), and culture.

Patients with cloudy fluid and clinical symptoms should receive empirical therapy, preferably guided by results of a Gram stain. If no organisms are visualized, vancomycin and either an aminoglycoside or third-generation cephalosporin with antipseudomonal activity should be given via the intraperitoneal route. Patients without cloudy fluid and with minimal symptoms may have therapy withheld pending culture results. Once the cause is identified by culture, changes in the therapeutic regimen may be needed. Oral rifampin may be added for *S. aureus* infections. Fungal peritonitis should be treated with a combination of oral flucytosine and intraperitoneal or oral fluconazole alone. The duration of therapy is a minimum of 14 days, with longer treatment of 21–28 days for episodes of *S. aureus* and *Pseudomonas*, and 28–42 days for fungi. Repeat episodes of peritonitis within 4 wk of previous therapy represent “apparently relapsing” peritonitis. If the patient responds to reinstitution of antimicrobial therapy, a course of up to 6 wk should be continued. In all cases, if the infection fails to clear on appropriate therapy or if a patient's condition is deteriorating, the catheter should be removed. Exit-site and tunnel infections may occur independently of peritonitis, or may precede it. Appropriate antibiotics should be administered on the basis of Gram stain and culture findings. Some experts recommend that the peritoneal catheter be removed if *Pseudomonas* or fungal organisms are isolated.

Orthopedic Prostheses.

Orthopedic prostheses are used infrequently in children although their use is increasing in limb salvage procedures for osteosarcoma. Infection most often follows introduction of microorganisms at surgery or via hematogenous spread. Early postoperative infection occurs within 2–4 wk of surgery with typical manifestations that include fever, pain, and local symptoms of wound infection. Rapid assessment, including isolation of the infecting organism, and antimicrobial treatment may allow salvage of the implant. Late chronic infection occurs more than 1 mo after surgery and is often caused by organisms of low virulence that contaminated the implant at the time of surgery. Typical manifestations include pain and deterioration in function. These infections respond poorly to antibiotic treatment and usually require removal of the implant. Hematogenous infections are most often observed 2 or more yr after surgery. As with other long-term implanted devices, the most common organisms are about equally divided between coagulase-negative staphylococci and *S. aureus*.

The use of systemic antibiotic prophylaxis, antibiotic-containing bone cement, and

operating rooms fitted with laminar airflow all have been proposed as beneficial in reducing infection. To date, results from clinical studies are conflicting.

Section 2 - *Gram-Positive Bacterial Infections*

Chapter 166 - *Staphylococcus*

James K. Todd

Staphylococci are hardy, aerobic, non–spore-forming, bacteria that are ubiquitous as normal flora of humans and animals and present on fomites in dust. They are resistant to heat and drying and may be recovered from nonbiologic environments weeks to months after contamination. These organisms are gram-positive and grow in clusters as aerobes or facultative anaerobes. Strains are classified as *Staphylococcus aureus* if they are coagulase-positive or as one of the many species of **coagulase-negative staphylococci** (e.g., *S. epidermidis, S. saprophyticus, S. haemolyticus*). Generally, *S. aureus* produces a yellow pigment and ß-hemolysis on blood agar and *S. epidermidis* produces a white pigment with variable hemolysis results, although definitive species confirmation requires further testing. *S. aureus* has many virulence factors that mediate various serious diseases, whereas coagulase-negative staphylococci tend to be less pathogenic unless an indwelling foreign body (e.g., intravascular catheter) is present.

166.1 Staphylococcus aureus

S. aureus is the most common cause of pyogenic infection of the skin; it also may cause furuncles, carbuncles, osteomyelitis, suppurative arthritis, wound infection, abscesses, pneumonia, empyema, endocarditis, pericarditis, meningitis, and toxin-mediated diseases, including food poisoning, scarlet fever, scalded skin syndrome, and toxic shock syndrome (TSS).

Etiology.

Disease may result from tissue invasion or injury caused by various toxins and enzymes. Strains of *S. aureus* can be identified by the virulence factors they produce and classified classically by means of bacteriophage group typing (groups I–IV,

miscellaneous) or, more recently, by molecular techniques. Strains within phage groups often have similar pathogenic potential (e.g., phage group I is associated with TSS, phage group II with scalded skin syndrome).

Adhesion of *S. aureus* to mucosal cells is mediated by **teichoic acid** in the cell wall, and exposure to the submucosa or subcutaneous sites increases adhesion to fibrinogen, fibronectin, collagen, and other proteins. Different strains of *S. aureus* produce many virulence factors (Table 166–1), which have one or more of four different roles: protect the organism from host defenses, localize infection, cause local tissue damage, and act as toxins affecting noninfected tissue sites.

TABLE 166.1-1 -- **Virulence Factors Produced by *Staphylococcus aureus* and Their Role in Disease**

Factor	Location	Action	Pathophysiology
Cell Wall Components			
Peptidoglycan	Cell wall		Aggressin, shock
Teichoic acids	Cell wall		Adhesion to epithelium
Slime (coagulase-negative)	Cell wall	Extracellular matrix	Cements and protects
Capsule	Cell wall	Extracellular matrix	Protects from phagocytosis
Protein A	Cell wall	Binds IgG	Protects phagocytosis
Clumping factor	Cell wall	Binds fibrin	Large clumps, blocks phagocytosis
Fibronectin-binding	Cell wall	Attaches to fibronectin	Attachment to cell
PBP2a	Cell wall	Alters penicillin binding	Methicillin resistance
Enzymes			
Catalase	Soluble	Catalyzes $H_2 O_2$	Inhibits PMN killing
Coagulase	Soluble	Clots plasma	Forms abscess wall
Leukocidin	Soluble	Destroys PMNs	Protects from phagocytosis
Hemolysins	Soluble	Cytotoxic	Tissue damage
Lipase	Soluble	Lipolysis	Skin infection
ß-Lactamase	Soluble	Penase	Penicillin G resistance
Toxins			
Enterotoxin A, B, C, D, E	Soluble	Vagal stimulator	Food poisoning (TSS)
Exfoliatin A, B	Soluble	Granular layer cleavage	Scalded skin syndrome
TSST-1	Soluble	TNF, IL-1 stimulator	TSS

TSST-1, toxic shock syndrome-1; PMN, polymorphonuclear neutrophil; $H_2 O_2$, hydrogen peroxide; TNF, tumor necrosis factor; IL-1, interleukin 1.

Most strains of *S. aureus* possess factors that protect the organism from host defenses. Many staphylococci produce a loose polysaccharide capsule, or **slime layer**, which may interfere with opsonophagocytosis. Clumping factor interacts with fibrinogen to cause large clumps of organism to form, interfering with effective phagocytosis. Production of **coagulase**, or **clumping factor**, differentiates *S. aureus* from *S. epidermidis* and other coagulase-negative staphylococci. Coagulase causes plasma to clot by interacting with fibrinogen; this may have an important role in localization of infection (i.e., abscess formation). **Protein A**, which is present in most strains of *S. aureus* but not in *S. epidermidis*, reacts specifically with IgG1, IgG2, and IgG4. It is located on the outermost coat of the bacterium and can absorb serum immunoglobulin, preventing antibacterial antibodies from acting as opsonins and thus inhibiting phagocytosis. Other enzymes elaborated by staphylococci include **catalase** (inactivates hydrogen peroxide, promoting intracellular survival), **penicillinase** or **ß-lactamase** (inactivates penicillin at the molecular level), and lipase (associated with skin infection). **Leukocidin**, which is produced by most strains of *S. aureus*, combines with the phospholipid of the phagocytic cell membrane, producing increased permeability, leakage of protein, and eventual death of the neutrophil and macrophage.

Many strains of *S. aureus* produce substances that cause local tissue destruction. A number of immunologically distinct hemolysins have been identified: **a-toxin** acts on cell membranes and causes tissue necrosis, injures human leukocytes, and produces aggregation of platelets and spasm of smooth muscle; **ß-hemolysin** degrades sphingomyelin, causing hemolysis of red blood cells; **d-hemolysin** disrupts membranes by a detergent-like action.

Many strains of *S. aureus* release exotoxins. **Exfoliatins A and B** are two serologically distinct proteins that produce localized (e.g., bullous impetigo) or generalized (e.g., scalded skin syndrome, scarlatiniform eruption) dermatologic complications (Chapter 647). Exfoliatins produce skin separation by splitting the desmosome and altering the intracellular matrix in the stratum granulosum.

One or more staphylococcal **enterotoxins (types A, B, C_1 , C_2 , D, E)** are elaborated by most strains of *S. aureus*. Ingestion of preformed enterotoxin A or B is associated with vomiting and diarrhea and, in some cases, with the development of profound hypotension. By 10 yr of age, almost all individuals have antibodies to at least one enterotoxin.

Toxic shock syndrome toxin-1 (TSST-1) is associated with TSS related to menstruation and focal staphylococcal infection. Enterotoxin A and enterotoxin B also may be associated with nonmenstrual TSS. TSST-1 induces production of interleukin-1 and tumor necrosis factor, resulting in hypotension, fever, and multisystem involvement.

Epidemiology.

Most neonates are colonized within the first week of life, and 20–30% of normal individuals carry at least one strain of *S. aureus* in the anterior nares.

The organisms may be transmitted from the nose to the skin, where colonization seems to be more transient. Repeated recovery of *S. aureus* from the skin suggests repeated transfer rather than persistent skin colonization. Persistent umbilical and perianal carriage occurs.

Transmission of *S. aureus* generally occurs by direct contact or by spread of heavy particles over a distance of =6 ft. Heavily colonized individual carriers are particularly effective disseminators. Autoinfection is common, and minor infections (e.g., styes, pustules, paronychia) may be the source of disseminated infection. Handwashing between patient contacts decreases the spread of staphylococci from patient to patient. Older children and adults are more resistant than neonates to colonization. Spread via fomites is rare.

Invasive disease may follow colonization. Antibiotic therapy with a drug to which *S. aureus* is resistant favors colonization and the development of infection. Other factors that increase the likelihood of infection include wounds, skin disease, ventriculoperitoneal shunts, intravenous or intrathecal catheterization, corticosteroid treatment, starvation, acidosis, and azotemia. Viral infections of the respiratory tract also may predispose to secondary bacterial infection with staphylococci.

Pathogenesis.

The development of staphylococcal disease is related to resistance of the host to infection and to virulence of the organism (Fig. 166–1). The intact skin and mucous membranes serve as barriers to invasion by staphylococci. Defects in the mucocutaneous barriers produced by trauma, surgery, foreign surfaces (e.g., sutures, shunts, intravascular catheters), and burns increase the risk of infection.

Infants may acquire type-specific humoral immunity to staphylococci transplacentally. Older children and adults develop antibodies to staphylococci as a result of intermittent minor infections of the skin and soft tissues. Antibodies acquired after immunization with *S. aureus* capsular material have been shown to temporarily reduce subsequent infection in dialysis patients. Antibody to the various *S. aureus* toxins appears to protect against those specific toxin-mediated diseases but not necessarily focal or disseminated *S. aureus* infection with the same organisms. There is some indication that disseminated *S. aureus* disease in previously healthy children may occur after a viral infection that suppresses neutrophil or respiratory epithelial cell function.

Individuals with congenital or acquired defects in the complement system required for chemotaxis, defective chemotaxis (Job, Chédiak-Higashi, and Wiskott-Aldrich syndromes), defective phagocytosis, and defective humoral immunity (antibodies required for opsonization), as well as those with an impaired intracellular bactericidal capacity, are at increased risk of infection with staphylococci. Patients with chronic granulomatous disease, in which phagocytosis proceeds normally but killing of ingested catalase-positive bacteria is severely impaired, are particularly susceptible to staphylococcal disease. Impaired mobilization of polymorphonuclear leukocytes has been documented in children with diabetic ketoacidosis and in healthy individuals after ingesting alcohol. Patients with HIV infection have neutrophils that are defective in their ability to kill *S. aureus* in vitro.

Clinical Manifestations.

The signs and symptoms vary with the location of the infection, which, although most commonly located on the skin, may involve any tissue. Disease states of various degrees of severity are generally a result of local suppuration, systemic dissemination with metastatic infection, or systemic effects of toxin production. Although the nasopharynx and skin of many persons may be colonized with *S. aureus*, disease due to this organism is relatively uncommon. Lesions, especially those of the skin, are considerably more prevalent among persons living in low socioeconomic circumstances and particularly among those in tropical climates.

NEWBORN.

Staphylococcus is an important cause of neonatal infections (Chapter 98).

SKIN.

Staphylococcus is an important cause of pyogenic skin infections, including impetigo contagiosa, ecthyma, bullous impetigo, folliculitis, hydradenitis, furuncles, carbuncles, staphylococcal scalded skin syndrome (i.e., Ritter disease), and a syndrome resembling the rash of scarlet fever. Infection may also complicate wounds or occur as superinfection of other noninfectious skin disease (e.g., eczema). Folliculitis, or pyoderma of the hair follicle, may extend to a deep-seated furuncle or carbuncle if more than one hair follicle is involved. Recurrent furunculosis is a disorder of unknown cause and is associated with repeated episodes of pyoderma over months to years. Patients should be evaluated for immune defects associated with recurrent infection, especially those involving neutrophil dysfunction. *Staphylococcus* is also an important cause of nosocomial skin infections (Chapter 283).

Figure 166.1-1 Relationship of virulence factors to diseases associated with *Staphylococcus aureus*.

RESPIRATORY TRACT.

Infections of the upper respiratory tract due to *S. aureus* are rare, considering the frequency with which this area is colonized. Otitis media (Chapter 630) and sinusitis (Chapter 365) due to *S. aureus* may occur rarely. Staphylococcal sinusitis is relatively common in children with cystic fibrosis or defects in white blood cell (WBC) function. Suppurative parotitis is a rare infection, but *S. aureus* is a common cause. Staphylococcal tonsillopharyngitis is rare in otherwise normal children. A membranous tracheitis that complicates viral croup may be infected with *S. aureus* but also by other organisms. Patients typically have high fever, leukocytosis, and evidence of severe upper airway obstruction. Direct laryngoscopy or bronchoscopy shows a normal epiglottis with subglottic narrowing and thick, purulent secretions within the trachea. Treatment requires antibiotics and careful airway management.

Pneumonia (Chapter 389) due to *S. aureus* may be primary (hematogenous) or secondary after a viral infection such as influenza. Hematogenous pneumonia may be secondary to septic emboli, right-sided endocarditis, or the presence of intravascular devices. Inhalation pneumonia is caused by alterations of mucociliary clearance, leukocyte dysfunction, or bacterial adherence initiated by a viral infection. More common are high fever, abdominal pain, tachypnea, dyspnea, and localized or diffuse bronchopneumonia or lobar disease. *S. aureus* causes a necrotizing pneumonitis; empyema, pneumatoceles, pyopneumothorax, and bronchopleural fistulas develop frequently. Staphylococcal pneumonia occasionally produces a diffuse interstitial disease characterized by extreme dyspnea, tachypnea, and cyanosis. Cough may be nonproductive. *S. aureus* is an important pathogen of pneumonia in patients with cystic fibrosis (Chapter 393).

SEPSIS.

Staphylococcal bacteremia and sepsis (Chapter 163) may be associated with any localized infection. The onset may be acute and marked by nausea, vomiting, myalgia, fever, and chills. Organisms may localize subsequently at any site but are found especially in the lungs, heart, joints, bones, kidneys, and brain. Even if appropriate antibiotic therapy is provided, patients may remain febrile and blood cultures may remain positive for 24–48?hr.

In some instances, especially in young adolescent males, disseminated staphylococcal disease occurs, characterized by fever, persistent bacteremia despite antibiotics, and focal involvement of two or more separate tissue sites (e.g., skin, bone, joint, kidney, lung, liver, heart). Endocarditis and septic thrombophlebitis must be ruled out.

MUSCLE.

Localized staphylococcal abscesses in muscle associated with elevation of muscle enzymes but without septicemia have been called tropical pyomyositis. Although this disorder has been reported most frequently from tropical areas, it also has occurred in the United States in otherwise healthy children. Multiple abscesses occur in 30–40% of cases. Prodromal symptoms may include coryza, pharyngitis, diarrhea, or prior trauma at the site of the abscess. Surgical drainage and appropriate antibiotic therapy are essential.

BONES AND JOINTS.

S. aureus is the most common cause of osteomyelitis and suppurative arthritis in children (Chapter 674).

CENTRAL NERVOUS SYSTEM.

Meningitis (Chapter 594.1) due to *S. aureus* is not common; it is associated with cranial trauma and neurosurgical procedures (e.g., craniotomy, cerebrospinal fluid [CSF] shunt placement) and less frequently with endocarditis, parameningeal foci (e.g., epidural or brain abscess), diabetes mellitus, or malignancy. The CSF profile in *S. aureus* meningitis is indistinguishable from that in other bacterial causes of meningitis.

HEART.

Infective endocarditis (Chapter 429) may follow staphylococcal bacteremia. *S. aureus* is a common cause of acute endocarditis on native valves. Perforation of heart valves, myocardial abscesses, heart failure, conduction disturbances, acute hemopericardium, purulent pericarditis, and sudden death may ensue.

KIDNEY.

S. aureus is a common cause of renal and perinephric abscess (Chapter 530) usually of hematogenous origin. Urinary tract infection due to *S. aureus* is unusual.

TOXIC SHOCK SYNDROME.

S. aureus is the principal cause of TSS (Chapter 166.2).

INTESTINAL TRACT.

Staphylococcal enterocolitis follows overgrowth of normal bowel flora by staphylococci. Although uncommon, this can follow use of broad-spectrum oral antibiotic therapy. Diarrhea is associated with blood and mucus.

Peritonitis associated with *S. aureus* in patients receiving long-term ambulatory peritoneal dialysis usually involves the catheter tunnel. Removal of the catheter is required to achieve a bacteriologic cure.

Food poisoning (Chapter 321) may be caused by ingestion of preformed enterotoxins preformed by staphylococci contaminating foods. Approximately 2–7?hr after ingestion of the toxin, sudden, severe vomiting begins. Watery diarrhea may develop, but fever is absent or low. Symptoms rarely persist longer than 12–24?hr. Rarely, shock and death may occur.

Diagnosis.

The diagnosis of staphylococcal infection depends on isolation of the organisms from nonpermissive sites such as skin lesions, abscess cavities, blood, or other sites of infection. Isolation from the nose or skin does not necessarily imply causation because these are normally colonized sites. The organisms can be grown readily in liquid and on solid media. After isolation, identification is made on the basis of Gram stain and coagulase, clumping factor, and protein A reactivity. Patterns of susceptibility to antibiotics should be assessed in serious cases.

Diagnosis of staphylococcal food poisoning generally is made on the basis of epidemiologic and clinical findings. Food suspected of contamination should be examined by Gram stain, cultured, and tested for enterotoxin. Enterotoxin testing can be performed by the Centers for Disease Control and Prevention.

DIFFERENTIAL DIAGNOSIS.

Skin lesions due to *S. aureus* and those due to group A streptococci may be indistinguishable. Staphylococcal pneumonia can be suspected on the basis of chest roentgenograms that may reveal pneumatoceles, pyopneumothorax, or lung abscess. These changes, suggesting a necrotizing pneumonitis, are not pathognomonic for staphylococcal infection and may be noted in patients with pneumonia due to other bacteria, including *Klebsiella* and many anaerobes. Fluctuant skin and soft tissue lesions also can be caused by many organisms, including *Mycobacterium tuberculosis*, atypical mycobacteria, *Bartonella henselae* (cat-scratch disease), *Francisella tularensis*, and various fungi.

Treatment.

Antibiotic therapy alone is rarely effective in individuals with undrained abscesses or with infected foreign bodies. Loculated collections of purulent material should be relieved by incision and drainage. Foreign bodies should be removed, if possible. Therapy always should be initiated with a penicillinase-resistant antibiotic because more than 90% of all staphylococci isolated, regardless of source, are resistant to penicillin.

For serious infections, parenteral treatment is indicated, at least at the outset, until symptoms are controlled. Serious staphylococcal infections, with or without abscesses, tend to persist and recur, necessitating prolonged therapy.

The antibiotic used as well as the dose, route, and duration of treatment depends on the site of infection, the response of the patient to treatment, and the sensitivity of the organisms recovered from blood or from local sites of infection. For most patients with serious staphylococcal infection, intravenous treatment is recommended until the patient has been afebrile for 72?hr and other signs of infection have disappeared. Oral therapy is continued for a total of 3 wk, longer in selected cases. Treatment of staphylococcal osteomyelitis (see Chapter 674), meningitis (see Chapter 594.1), and endocarditis (see Chapter 429) are discussed in their respective chapters.

In all of these infections, oral treatment may be provided to complete the course of treatment after an initial period of parenteral therapy. Dicloxacillin (50–100?mg/kg/24?hr divided qid PO) and cephalexin (25–100?mg/kg/24?hr divided tid–qid PO) are absorbed well orally and effective. Amoxicillin-clavulanate (40–80?mg amoxicillin/kg/24?hr divided tid PO) also is effective. The duration of oral therapy depends on the response as determined by the clinical, roentgenographic, and laboratory findings.

Skin and soft tissue infection and minor upper respiratory tract infection may be managed by oral therapy alone or by an initial brief course of antibiotics provided parenterally, followed by oral medication.

Individuals with hypersensitivity to penicillin and its derivatives must be treated with other antibiotics or desensitized to the penicillin derivative to be used. About 5% of penicillin-sensitive children are also sensitive to cephalosporins. Clindamycin (30–40?mg/kg/24?hr divided tid–qid PO) has proved effective for the treatment of skin, soft tissue, bone, and joint infections due to *S. aureus* if the organism is susceptible. Clindamycin is bacteriostatic and should *not* be used to treat endocarditis, brain abscess, or meningitis due to *S. aureus*. Vancomycin (40–60?mg/kg/24?hr divided q 6?hr IV) can be used to treat penicillin-sensitive individuals with serious *S. aureus* infections. Serum levels of vancomycin should be monitored, with peak concentrations of 20–40?µg/mL. Vancomycin or teicoplanin (a vancomycin derivative) should be used to treat serious staphylococcal infections when the organism is known or suspected to be resistant to semisynthetic penicillin derivatives, so-called **methicillin-resistant *S. aureus* (MRSA)**. Community acquired MRSA strains are becoming more common throughout the United States even in children without pre-existing risk factors. Rare vancomycin-intermediate strains have also been reported mostly in patients being treated with vancomycin. Despite in vitro susceptibility of *S. aureus* to ciprofloxacin and other quinolone antibiotics, these agents should not be used in serious staphylococcal infections, because their use has not consistently been associated with high cure rates and the quinolones are not recommended for use in patients younger than 18 years of age.

Serious staphylococcal infections (e.g., septicemia, endocarditis, central nervous system infections) can be treated with intravenous nafcillin, oxacillin, or, in penicillin-allergic children, vancomycin or imipenem. Rifampin or gentamicin may be added for synergy.

METHICILLIN-RESISTANT *STAPHYLOCOCCUS AUREUS*.

MRSA has emerged as a major nosocomial pathogen. Patients at risk for MRSA infection are those with serious illnesses (e.g., burns, surgical wounds, chronic venous access, lengthy hospitalizations, premature infants) or in contact with other MRSA-infected patients.

Resistance to semisynthetic penicillins is thought to be related to a novel **penicillin-binding protein (PB2A)** that is relatively insensitive to antibiotics containing a ß-lactam ring. MRSA strains appear to be as virulent as their

methicillin-sensitive counterparts. Vancomycin and its derivative, teicoplanin, are highly effective in the treatment of these infections. Vancomycin is the drug of choice if MRSA is considered a possible cause of serious infection or if MRSA has been isolated. MRSA is also resistant to cephalosporins and imipenem but often remains sensitive to the quinolones. Linezolid and quinupristin-dalfopristin may be useful for serious *S. aureus* infections highly resistant to other antibiotics.

When MRSA is recovered, strict isolation of affected patients has been shown to be the most effective method for preventing nosocomial spread of infection. Thereafter, control measures should be directed toward identification of new isolates and strict isolation of newly colonized or infected patients. It also may be necessary to identify colonized hospital personnel and eradicate carriage in affected individuals.

Strains of *S. aureus* resistant to vancomycin with limited other treatment options have been reported, emphasizing the need for restricting the prescription of unnecessary antibiotics and the importance of isolation of the causative organism and susceptibility testing in serious infections.

Prognosis.

Untreated staphylococcal septicemia is associated with a mortality rate of =80%. Mortality rates have been reduced significantly by appropriate antibiotic treatment. Staphylococcal pneumonia can be fatal at any age but is more likely to be associated with high morbidity and mortality in young infants or in patients whose therapy has been delayed.

A total WBC count <5,000/mm^3 or a polymorphonuclear leukocyte response of <50% is a grave prognostic sign. Prognosis also may be influenced by numerous host factors, including nutrition, immunologic competence, and the presence or absence of other debilitating diseases. In most cases with abscess formation, surgical drainage is necessary.

Prevention.

Staphylococcal infection is transmitted primarily by direct contact. Strict attention to handwashing techniques is the most effective measure for preventing the spread of staphylococci

---

from one individual to another (Chapter 283). Use of a detergent containing an iodophor, chlorhexidine, or hexachlorophene is recommended. In hospitals or other institutional settings, all persons with acute staphylococcal infections should be isolated until they have been treated adequately. There should be constant surveillance for nosocomial staphylococcal infections within hospitals.

Patients with recurrent staphylococcal furunculosis may be treated with hexachlorophene washes and dicloxacillin or clindamycin and nasal mupirocin to prevent recurrences.

Food poisoning (Chapter 321) may be prevented by excluding individuals with staphylococcal infections of the skin from the preparation and handling of food. Prepared foods should be eaten immediately or refrigerated appropriately to prevent multiplication of staphylococci with which the food may have been contaminated.

166.2 Toxic Shock Syndrome

TSS is an acute multisystem disease characterized by high fever, hypotension, vomiting, diarrhea, myalgias, nonfocal neurologic abnormalities, conjunctival hyperemia, strawberry tongue, and an erythematous rash with subsequent desquamation on the hands and feet.

Etiology.

TSS is caused by TSST-1 producing strains of *S. aureus*, which may colonize the vagina or cause focal sites of staphylococcal infection.

Epidemiology.

Many cases occur in menstruating women who are 15–25 yr of age and who use tampons or other vaginal devices (e.g., diaphragm, contraceptive sponge). TSS, however, also occurs in children, nonmenstruating women, and men. Nonmenstrual TSS has occurred with *S. aureus* colonization of nasal packing or infections including wound infections, sinusitis, tracheitis, pneumonia, empyema, abscesses, burns, osteomyelitis, and primary bacteremia. Without antimicrobial therapy, menstrual TSS has a high recurrence rate (30%), with secondary cases being milder and occurring within 3 mo of the original episode; the overall mortality of treated cases is 3%.

Pathogenesis.

A majority of *S. aureus* strains isolated from confirmed cases are phage group I and produce a number of extracellular toxins. The primary toxin associated with TSS is TSST-1, which causes massive loss of fluid from the intravascular space directly or after production of interleukin-1 and tumor necrosis factor. However, TSST-1–negative strains have been isolated from patients with TSS, suggesting that other toxins (primarily the enterotoxins) have a role in TSS (especially nonmenstrual). Epidemiologic and in vitro studies suggest that these toxins are selectively produced in a clinical environment consisting of a neutral pH, a high P_{CO_2} , and an “aerobic” P_{O_2} , which are the conditions found in the vagina with tampon use during menstruation. This may explain why 90% of adults have antibody to TSST-1 without a history of clinical TSS—that is, they became colonized with a toxin-producing organism at a site (e.g., anterior nares) where low-grade or inactive toxin exposure resulted in an immune response without disease. The risk factors for symptomatic disease require a nonimmune host colonized with a toxin-producing organism, which is exposed to focal growth conditions (e.g., menstruation plus tampon use or abscess), which induce toxin production.

Clinical Manifestations.

The diagnosis of TSS is based on clinical manifestations (Box 166–1). The onset is abrupt, with high fever, vomiting, and diarrhea, and is accompanied by sore throat, headache, and myalgias. A diffuse erythematous macular rash (sunburn-like or scarlatiniform) appears within 24?hr and may be associated with hyperemia of pharyngeal, conjunctival, and vaginal mucous membranes. A strawberry tongue is

Box 166.2-1. Diagnostic Criteria of Staphylococcal Toxic Shock Syndrome

MAJOR CRITERIA (ALL REQUIRED)

Acute fever; temperature >38.8°C

Hypotension (orthostatic or shock)

Rash (erythroderma with late desquamation)

MINOR CRITERIA (ANY 3)

Mucous membrane inflammation

Vomiting, diarrhea

Liver abnormalities

Renal abnormalities

Muscle abnormalities

Central nervous system abnormalities

Thrombocytopenia

EXCLUSIONARY CRITERIA

Absence of another explanation

Negative blood cultures (except for *S. aureus*)

EXCLUSIONARY CRITERIA

Absence of another explanation

Negative blood cultures (except for *S. aureus*)

common. Symptoms often include alterations in the level of consciousness, oliguria, and hypotension, which in severe cases may progress to shock and disseminated intravascular coagulation. Complications including adult respiratory distress syndrome, myocardial failure, and renal failure are commensurate with the degree of shock. Recovery occurs within 7–10 days and is associated with desquamation, particularly of palms and soles; hair and nail loss have also been observed after 1–2 mo. Many cases of apparent scarlet fever without shock may be caused by TSST-1–producing *S. aureus* strains.

Diagnosis.

There is no specific laboratory test; appropriate selective tests reveal involvement of multiple organ systems including the hepatic, renal, muscular, gastrointestinal, cardiopulmonary, and central nervous systems. Bacterial cultures of the associated focus (e.g., vagina, abscess) before administration of antibiotics usually yield *S. aureus*, although this is not a required element of the definition.

DIFFERENTIAL DIAGNOSIS.

Group A *Streptococcus* can cause a similar TSS-like illness, termed **streptococcal TSS** (Chapter 168), which is often associated with streptococcal bacteremia or a focal streptococcal infection such as cellulitis or pneumonia.

Kawasaki disease closely resembles TSS clinically but is usually not as severe or rapidly progressive. Both are associated with fever unresponsive to antibiotics, hyperemia of mucous membranes, and an erythematous rash with subsequent desquamation. Many of the clinical features of TSS, however, are absent or rare in Kawasaki disease, including diffuse myalgia, vomiting, abdominal pain, diarrhea, azotemia, hypotension, adult respiratory distress syndrome, and shock (Chapter 156). Kawasaki disease typically occurs in children younger than 5 yr—some cases of “adult Kawasaki disease” may be TSS. Scarlet fever, Rocky Mountain spotted fever, leptospirosis, toxic epidermal necrolysis, sepsis, and measles must also be considered in the differential diagnosis.

Treatment.

Parenteral administration of a ß-lactamase–resistant antistaphylococcal antibiotic (e.g., nafcillin or a first-generation cephalosporin) is recommended after appropriate cultures have been obtained. The addition of clindamycin in severe or unresponsive cases may terminate toxin production. Drainage of the vagina, by removal of any retained tampons in menstrual TSS, and of focally infected sites in nonmenstrual TSS is important for successful treatment. Antistaphylococcal therapy may also reduce the risk of recurrence in menstrual TSS.

Fluid replacement should be aggressive to prevent or treat hypotension, renal failure, and cardiovascular collapse. Inotropic agents may be needed to treat shock;

corticosteroids and intravenous immunoglobulin are reserved for severe cases.

Prevention.

The low risk of acquiring TSS (1–2 cases/100,000 menstruating women) may be reduced by not using tampons or by using them intermittently during each menstrual period. If a fever, rash, or dizziness develops during menstruation, any tampon should be removed immediately and medical attention sought.

166.3 Coagulase-Negative Staphylococci

S. epidermidis is just one of many recognized species of coagulase-negative staphylococci (CONS) affecting or colonizing humans. Originally thought to be avirulent commensal bacteria, CONS is now known to produce nosocomial infections in patients with indwelling foreign devices (intravenous catheters—sepsis; hemodialysis shunts and grafts—sepsis; CSF shunts—meningitis; peritoneal dialysis catheters—peritonitis; pacemaker wires and electrodes—pocket infection; prosthetic cardiac valves—endocarditis; urinary catheters—pyelonephritis; prosthetic joints—arthritis), surgical trauma (sternal osteomyelitis, endophthalmitis), immunocompromised states (malignancy, granulocytopenia), and, rarely, community-acquired disease in patients with no underlying disease (urinary tract infection, osteomyelitis). CONS is a common cause of nosocomial neonatal infection. *S. haemolyticus*, another CONS species, is an important cause of invasive infection and may develop resistance to vancomycin and teicoplanin.

Epidemiology.

CONS consists of normal inhabitants of the human skin, throat, mouth, vagina, and urethra. *S. epidermidis* is the most common and persistent species, representing 65–90% of staphylococci present on the skin and mucous membranes. Colonization, sometimes with strains acquired from hospital staff, precedes infection; alternatively, direct inoculation during surgery may initiate infection of CSF shunts, prosthetic valves, or indwelling vascular lines. For epidemiologic purposes, CONS can be identified on the basis of phage typing, antibiotic sensitivities, slime layer production, and molecular DNA methods.

Pathogenesis.

S. epidermidis produces an **exopolysaccharide** protective biofilm, or **slime layer**, that surrounds the organism and may enhance adhesion to foreign surfaces, resist phagocytosis, and impair penetration of antibiotics.

Clinical Manifestations.

The low virulence of CONS usually requires the presence of another factor, such as immune compromise or a foreign body, for development of clinical disease.

BACTEREMIA.

CONS, specifically *S. epidermidis*, are the most common cause of nosocomial bacteremia. In neonates, CONS bacteremia, with or without a central venous catheter, may be manifested as apnea, bradycardia, temperature instability, abdominal distention, hematochezia, meningitis in the absence of CSF pleocytosis, cutaneous abscesses, and persistence of positive blood cultures for as long as 2 wk despite adequate antimicrobial therapy. CONS bacteremia in patients with bone marrow transplantation and malignancy (e.g., leukemia, lymphoma) is associated with neutropenia, central venous access (Hickman or Broviac catheters), and gastrointestinal colonization. In most circumstances, CONS bacteremia is indolent and is not usually associated with overwhelming septic shock.

ENDOCARDITIS.

Infection of native heart valves or the right atrial wall secondary to an infected thrombosis at the end of a central line may produce endocarditis. *S. epidermidis* and other CONS may also produce native valve subacute indolent endocarditis in previously normal patients without a central venous catheter. CONS is a common cause of prosthetic valve endocarditis, presumably due to inoculation at the time of surgery. Infection of the valve sewing ring, with abscess formation and dissection, produces valve dysfunction, dehiscence, arrhythmias, or valve obstruction. See Chapter 443 for clinical manifestations.

CENTRAL VENOUS CATHETER INFECTION.

Central venous catheters become infected through the exit site and subcutaneous tunnel, which provide a direct path to the bloodstream. *S. epidermidis* is the most common CONS, owing in part to its high rate of cutaneous colonization. Line sepsis is manifested as fever, leukocytosis, tenderness, and erythema at the exit site or along the subcutaneous tunnel, and catheter thrombosis.

CEREBROSPINAL FLUID SHUNTS.

S. epidermidis, introduced at the time of surgery, is the most common pathogen associated with CSF shunt meningitis. Most (70–80%) infections occur within 2 mo of the operation and are manifested by signs of meningeal irritation, fever, increased intracranial pressure (headache), and peritonitis due to the intra-abdominal position of the distal end of the shunt tubing.

URINARY TRACT INFECTION.

CONS causes asymptomatic urinary tract infection in hospitalized patients with urinary catheters and after urinary tract surgery or transplantation. *S. saprophyticus* is one of the most common causes of primary urinary tract infections in boys and girls. Manifestations are similar to those characteristic of urinary tract infection due to *Escherichia coli* (Chapter 530).

S. epidermidis is the most common pathogen producing peritonitis in patients on continuous ambulatory peritoneal dialysis. Manifestations of infection include abdominal pain, fever, >100 neutrophils/mm^3 , and a positive culture or Gram stain.

Diagnosis.

Because *S. epidermidis* is a common skin inhabitant and may contaminate poorly collected blood cultures, differentiating bacteremia from contamination may be difficult. True bacteremia should be suspected when blood cultures grow rapidly (within 24?hr), when two or more blood cultures are positive with the same CONS, when the peripheral venous blood culture has a quantitative colony count comparable to that drawn from a central venous catheter, and when clinical and laboratory signs and symptoms compatible with CONS sepsis are present and subsequently resolve with appropriate therapy. No blood culture that is positive for CONS in a neonate or patient with intravascular catheter should be considered contaminated without careful assessment of the foregoing criteria and examination of the patient. Before initiating presumptive antimicrobial therapy in such patients it is always prudent to draw two separate blood cultures to facilitate subsequent interpretation if CONS is grown.

Treatment.

Most CONS strains are resistant to methicillin. Vancomycin is the drug of choice for methicillin-resistant strains. The new quinolones and teicoplanin have some activity against CONS, and the addition of rifampin or gentamicin to vancomycin may increase antimicrobial efficacy. In many cases of CONS infection associated with foreign bodies, the catheter, valve, or shunt must be removed to ensure a cure. Prosthetic heart valves and CSF shunts usually have to be removed to treat the infection adequately.

Antibiotic therapy given through an infected central venous catheter (through each lumen) may effectively cure CONS line sepsis. If the catheter or reservoir is no longer needed, it should be removed. Unfortunately, this is not always possible owing to the therapeutic requirements of the underlying disease (nutrition for short bowel syndrome, chemotherapy for malignancy). A trial of intravenous vancomycin is indicated to attempt to preserve the use of the central line.

Peritonitis due to *S. epidermidis* in patients on continuous ambulatory peritoneal dialysis is another infection that may be treated with intravenous or intraperitoneal antibiotics without removing the dialysis catheter. If the organism is resistant to methicillin, vancomycin adjusted for renal function is appropriate therapy.

Prognosis.

Most episodes of CONS bacteremia respond successfully to antibiotics and removal of any foreign body that is present. Poor prognosis is associated with malignancy, neutropenia, and infected prosthetic or native heart valves. CONS increases morbidity, the duration of hospitalization, and mortality rates among patients with underlying complicated illnesses.

Chapter 167 - *Streptococcus pneumoniae* (Pneumococcus)

Jon S. Abramson
Gary D. Overturf

Streptococcus pneumoniae, or pneumococcus, frequently colonizes the upper respiratory tract and may cause upper respiratory tract infection (e.g., otitis media, sinusitis) or invasive disease (e.g., pneumonia, bacteremia, meningitis). *S. pneumoniae* is the most common cause of community-acquired bacterial pneumonia and otitis media. With universal immunization with conjugated *Haemophilus influenzae* type b vaccines, *S. pneumoniae* has become the second most common cause of bacterial meningitis in children and the most common cause of meningitis in adults. The significance of this agent has been emphasized by worldwide emergence of penicillin and multidrug-resistant strains. Introduction of a universal recommendation to give infants the pneumococcal heptavalent conjugate vaccine may have marked effects on the epidemiology of this organism by reducing nasopharyngeal carriage and the burden of pneumococcal disease.

Etiology.

S. pneumoniae is a gram-positive, lancet-shaped, encapsulated diplococcus, occurring occasionally as individual cocci or in chains. Ninety serotypes have been identified by type-specific capsular polysaccharides. Antisera to some pneumococcal polysaccharides cross react with those of other pneumococcal types and define serogroups (e.g., 6A and 6B), or other bacteria (e.g., *Escherichia coli*, group B *Streptococcus*, and *H. influenzae* type b). Only “smooth,” or encapsulated, strains cause serious disease in humans. Capsular material impedes phagocytosis. Virulence is related in part to capsular size, but pneumococcal types with capsules of the same size may vary widely in virulence.

On solid media, *S. pneumoniae* forms unpigmented, umbilicated colonies surrounded by a zone of incomplete (a) hemolysis. *S. pneumoniae* is bile soluble (i.e., 10% deoxycholate) and Optochin-sensitive. Pneumococcal capsules can be microscopically visualized and typed by exposing organisms to type-specific antisera that combine with their unique capsular polysaccharide, rendering the capsule refractile (**Quellung reaction**). Specific antibodies to capsular polysaccharide confer protection on the host, promoting opsonization and phagocytosis. **C substance**, a

cell wall antigen that is related to the pneumococcal species rather than a specific serotype, consists of a teichoic acid-containing phosphocholine and galactosamine-6-phosphate. C substance precipitates with a ß-globulin, the C-reactive protein, which activates complement, enhancing phagocytosis.

Epidemiology.

Most healthy individuals carry *S. pneumoniae* in their upper respiratory tract; >90% of children between 6 mo and 5 yr of age harbor *S. pneumoniae* in the nasopharynx at some time. Serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F constitute the majority of invasive isolates in children and, of these, 6B, 9V, 14, and 19F are frequently not susceptible to penicillin. A single serotype usually is carried for extended periods (45 days–6 mo). Carriage does not consistently induce local or systemic immunity sufficient to prevent later reacquisition of the same serotype. Rates of pneumococcal carriage peak during the first 2 yr of life and decline gradually thereafter. Carriage rates are highest in institutional settings and during the winter, and rates are lowest in summer. Nasopharyngeal carriage of pneumococci is common among young children attending out-of-home care with rates of 21–59% in point prevalence estimates and 65% in longitudinal studies.

S. pneumoniae is the most frequent cause of bacteremia, bacterial pneumonia, and otitis media, and the second most common cause of meningitis in children. The decreased ability in children <2 yr of age to produce antibody against polysaccharide antigens and the high frequency of colonization may explain an increased susceptibility to pneumococcal infection and the decreased effectiveness of polysaccharide vaccines. Males are more commonly affected than females. Native American and African-American children have rates of invasive disease that are 2–10-fold that of other healthy children. Rates of invasive pneumococcal disease in the United States peak at 6–11 mo of age, with attack rates of >540/100,000 in healthy children before the universal use of pneumococcal conjugate immunization.

Pneumococcal disease generally occurs sporadically, but pneumococci can be spread from person to person by respiratory droplet transmission. The frequency and severity of pneumococcal disease are increased in patients with sickle cell disease, asplenia, deficiencies in humoral (B cell) and complement mediated immunity, HIV infection, and certain malignancies (e.g., leukemia, lymphoma); chronic heart, lung, or renal disease (particularly the nephrotic syndrome); and cerebrospinal fluid leak syndromes.

Pathogenesis.

Invasion of the host is precipitated by a number of factors. Nonspecific defense mechanisms, including the presence of other bacteria in the nasopharynx, may limit multiplication of pneumococci. Aspiration of secretions containing pneumococci is hindered by epiglottic reflex and by respiratory epithelial cilia, which move infected mucus toward the pharynx. Similarly, normal ciliary flow of fluid from the middle ear

through the eustachian tube and sinuses to the nasopharynx usually prevents infection with nasopharyngeal flora, including pneumococci. Interference with these normal clearance mechanisms by allergy, viral infection, or irritants (e.g., smoke) may allow colonization and subsequent infection with these organisms in otherwise normally sterile sites.

Virulent pneumococci are intrinsically resistant to phagocytosis by alveolar macrophages. Pneumococcal disease frequently is facilitated by viral respiratory tract infection, which may produce mucosal injury, diminish epithelial ciliary activity, and depress the function of alveolar macrophages and neutrophils. Phagocytosis may be impeded by respiratory secretions and alveolar exudate. In tissues, pneumococci multiply and spread through the lymphatics or bloodstream (bacteremia) or, less commonly, by direct extension from a local site of infection (e.g., sinuses). The severity of disease is related to the virulence and number of organisms causing bacteremia, and to integrity of specific host defenses. A poor prognosis correlates with very large numbers of pneumococci and high concentrations of capsular polysaccharide in the circulation and cerebrospinal fluid.

Deficiency of many of the complement components is associated with recurrent pyogenic infection, including those caused by *S. pneumoniae*. The increased frequency of pneumococcal disease in asplenic persons is related to both deficient opsonization of pneumococci as well as to absence of the filtering function of the spleen on circulating bacteria. Invasive pneumococcal disease is 30–100-fold more prevalent in children with sickle cell disease and other hemoglobinopathies and in children with congenital or surgical asplenia. This risk is greatest in infants <2 yr of age when antibody production is poor. Children with sickle cell disease have deficits in the antibody-independent properdin (alternative) pathway of complement activation, in addition to functional asplenia. Both pathways contribute to antibody-independent and antibody-dependent opsonophagocytosis of pneumococci. With advancing age (e.g., >5 yr), children with sickle cell disease produce anticapsular antibody, augmenting antibody-dependent opsonophagocytosis and greatly reducing, but not eliminating, the risk of severe pneumococcal disease. The efficacy of phagocytosis also is diminished in patients with B- and T-cell immunodeficiency syndromes (e.g., agammaglobulinemia or severe combined immune deficiency) and is largely caused by a deficiency of opsonic anticapsular antibody. These observations suggest that opsonization of pneumococci depends on the alternative complement pathway in antibody-deficient persons and that recovery from pneumococcal disease depends on the development of anticapsular antibodies that act as opsonins, enhancing phagocytosis and killing of pneumococci. Children with HIV infection also have high rates of invasive pneumococcal infection similar to or greater than that of children with sickle cell disease.

In the lungs and other body tissues, the spread of infection is facilitated by the antiphagocytic properties of the pneumococcal capsule. Surface fluids of the respiratory tract contain only small amounts of IgG and are deficient in complement; both factors promote opsonization of pneumococci. During inflammation, there is an influx of IgG, complement, and neutrophils. Although phagocytosis of bacteria by neutrophils may occur, normal human serum may not opsonize pneumococci and facilitate phagocytosis by alveolar macrophages. The sequence of events evolves over 7–10 days, but can be modified by appropriate antibiotic therapy.

Clinical Manifestations.

The signs and symptoms of pneumococcal infection are related to the anatomic site of disease. Common clinical syndromes include pneumonia (Chapter 389), otitis media (Chapter 630), sinusitis (Chapter 365), occult bacteremia in infants and young children (Chapter 162), and sepsis (Chapter 163). Before routine use of the conjugated pneumococcal vaccines, pneumococci caused >80% of bacteremias in infants 2–36 mo of age with fever without an identifiable source. Pneumococcal abscesses of the upper airway (Chapter 367), laryngotracheobronchitis (Chapter 371), and peritonitis (Chapter 352.1) occur, but are rare infections. Local complications of infection may occur, causing empyema, pericarditis, mastoiditis, epidural abscess, or meningitis. Colonizing pneumococci may spread through the eustachian tube, producing otitis media, and aspiration of infected upper respiratory secretions may produce pneumonia. Bacteremia may be followed by meningitis (Chapter 594.1), osteomyelitis and suppurative arthritis (Chapter 674), endocarditis (Chapter 429), and rarely, brain abscess (Chapter 595). Hemolytic-uremic syndrome (Chapter 510) and disseminated intravascular coagulation also occur as rare complications of pneumococcal infections.

Diagnosis.

The diagnosis of pneumococcal infection is established by recovery of *S. pneumoniae* from the site of infection or the blood. Although pneumococci may be found in the nose or throat of patients with otitis media, pneumonia, septicemia, or meningitis, they may not be related causally to their disease and therefore throat cultures are not helpful for diagnosis. Blood cultures should be obtained in children with pneumonia, meningitis, arthritis, osteomyelitis, peritonitis, pericarditis, or gangrenous skin lesions. Blood cultures can also be useful in children who are <36 mo of age who have fever without localizing signs of infection, especially those with clinical toxicity or significant leukocytosis (Chapter 162).

Pneumococci can be identified in body fluids as gram-positive, lancet-shaped diplococci. Early in the course of pneumococcal meningitis, many bacteria may be seen in a relatively acellular cerebrospinal fluid. With current methods of continuously monitored blood culture systems, the average time to isolation of pneumococcal organisms is 14–15?hr and rarely >24?hr. Commercially available pneumococcal latex agglutination tests for urine or other sterile body sites suffer from poor sensitivity and add very little to standard cultures and Gram-stained fluids. Leukocytosis often is pronounced, with total white blood cell counts frequently >15,000/mm^3 , although severe cases (including meningitis) may have a low white count with a shift to the left.

Before the emergence of penicillin nonsusceptible organisms, penicillin was the treatment of choice for presumed pneumococcal infection. The incidence of intermediate and high-level penicillin resistance and multidrug resistance (e.g., penicillin, tetracycline, chloramphenicol, rifampin, erythromycin, sulfonamides, or clindamycin) have increased during the past decade. In North America, up to 40% of isolates from sterile body sites are nonsusceptible to penicillin G with as many as 50% of these isolates being highly resistant. Multiply resistant strains have been identified in South Africa, Spain, Great Britain, Australia, and the United States.

Resistance to antibiotics is most often noted in pneumococcal serogroups 6, 9, 14, 19, and 23, which are the most frequent cause of pneumococcal disease in children.

Problems in treatment may be encountered by organisms that are intermediately resistant to penicillin, defined as minimum inhibitory concentration (MIC) 0.1–1.0?mg/L, or organisms that are highly resistant to penicillin, defined as MIC =2.0?mg/L, and organisms that are resistant to several antibiotics. All isolates from children with severe infections should be tested for antibiotic susceptibility. A screening test for susceptibility to penicillin can be performed with a 1-µg oxacillin disk diffusion test, but the use of an E-test or MIC is the preferred method for measuring penicillin susceptibility because of greater specificity, particularly for intermediately resistant strains. Many penicillin-resistant strains are also resistant to the extended spectrum cephalosporins (e.g., ceftriaxone, cefotaxime). Resistance to vancomycin has not been reported.

Empirical treatment of pneumococcal disease should be based on knowledge of susceptibility patterns in specific communities.

Penicillin G is the drug of choice for penicillin-susceptible strains. Oral penicillin V (50–100?mg/kg/24?hr divided q 6–8?hr PO) for minor infections, intravenous penicillin G (200,000–250,000?U/kg/24?hr divided q 4–6?hr IV) for bacteremia or pneumonia, and intravenous penicillin G (300,000?U/kg/24?hr divided q 4–6?hr IV) for meningitis are recommended. For serious infections (e.g., meningitis) with strains that are intermediately resistant to penicillin and for all infections with highly penicillin-resistant strains, vancomycin (60?mg/kg/24?hr divided q6?hr IV) is the treatment of choice until the susceptibilities to other antibiotics are known. Rifampin (20?mg/kg/24?hr divided q 12?hr PO) may be added in severe or unresponsive cases. Resistance to the third-generation cephalosporins, such as cefotaxime and ceftriaxone, is common in penicillin-resistant strains, and treatment failures have been reported when treating meningitis. However, for many intermediately resistant organism, cefotaxime (225–300?mg/kg/ 24?hr divided q 8?hr IV) or ceftriaxone (100?mg/kg/24?hr divided q 12–14?hr IV) may be added or substituted for vancomycin depending upon the results of susceptibility testing.

For invasive infections outside the central nervous system (e.g., lobar pneumonia with or without bacteremia), high-dose cefotaxime and ceftriaxone are usually effective, even for those infections caused by cephalosporin intermediate or resistant strains (MIC =2.0?mg/L). For susceptible strains, clindamycin, erythromycin, cephalosporins, trimethoprim-sulfamethoxazole, and chloramphenicol may provide effective alternative therapy, depending on the site of infection (e.g., clindamycin is often effective for pneumococcal infections other than meningitis), for individuals who are allergic to penicillin. Higher doses of amoxicillin-clavulanate (80–90?mg amoxicillin/kg/day divided tid PO), with modified ratios of amoxicillin and clavulanate to permit higher amoxicillin dosing, have been successful in the treatment of otitis media caused by resistant strains.

Prognosis.

Prognosis depends on the integrity of host defenses, virulence and numbers of the infecting organism, the age of the host, the site and extent of the infection, and the adequacy of treatment.

Prevention.

Immunologic responsiveness and efficacy following administration of pneumococcal polysaccharide vaccines is unpredictable in children <2 yr of age. Two licensed pneumococcal vaccines contain purified polysaccharide of 23 pneumococcal serotypes responsible for >95% of cases of invasive disease. The clinical efficacy of these vaccines is controversial and studies have yielded conflicting results. Polysaccharide antigens 6A, 14, 19F, and 23F frequently produce childhood disease and are poorly immunogenic in children <5 yr of age.

In contrast, pneumococcal polysaccharide vaccines conjugated to various proteins (e.g., heptavalent pneumococcal polysaccharide conjugated to CRM_{197}) provoke “protective” antibody responses in 90% of infants given these vaccines at 2, 4, and 6 mo of age, and greatly enhanced responses (e.g., immunologic memory) are apparent after “booster” doses given at 12–15 mo of age. In addition, protein conjugate–polysaccharide vaccines reduce nasopharyngeal carriage of vaccine serotypes by up to 60–70%. The currently available heptavalent vaccine contains conjugated capsular polysaccharides of serotypes 4, 6B, 9V, 14, 19F, 23F, and 18C. In efficacy trials in the United States, infant immunization with this vaccine decreased invasive infections by >93% and lobar pneumonias by >73%. Its administration was associated with a 6–7% decrease in otitis media, but greater reduction in complications of otitis media such as tympanostomy tube placement. Adverse events after the administration of heptavalent CRM_{197} conjugate vaccines have included local swelling and redness and slightly increased rates of fever, when used in conjunction with other childhood vaccines. It is likely that vaccines with increased numbers of polysaccharide serotypes, or different protein conjugates, will be licensed in the future.

Immunization with the conjugate polysaccharide vaccine is recommended for all infants in a schedule of four doses administered at 2, 4, 6, and 12–15 mo of age. The number of required immunizations is reduced for children 6–24 mo of age starting immunizations. High-risk children =2 yr of age, such as those with asplenia, sickle cell disease, some types of immune deficiency (e.g., antibody deficiencies), HIV infection, or chronic lung, heart, or kidney disease (including nephrotic syndrome), may benefit also from the 23-valent polysaccharide vaccine. After the initial immunization, a single supplemental dose of polysaccharide vaccine may be used 3 yr after the first dose for children <10 yr of age at the time of revaccination, or it may be used at 5 yr after the first dose for children 10 yr of age or older at the time of revaccination.

Immunization with pneumococcal vaccines also may prevent pneumococcal disease caused by nonvaccine serotypes that are serotypically related to a vaccine strain (e.g., 6A and 6B). However, because current vaccines do not eliminate all pneumococcal invasive infections, penicillin prophylaxis is recommended for children at high risk of invasive pneumococcal disease, including children with asplenia or sickle cell disease. Penicillin V potassium (125?mg bid PO for children <3 yr; 250?mg bid PO for children =3 yr) substantially decreases the incidence of pneumococcal sepsis in children with sickle cell disease. Once monthly intramuscular benzathine penicillin G (600,000?U?q 3–4 wk IM for children <60?lb; 1,200,000?U?q 3–4 wk IM for children =60?lb) may also provide adequate prophylaxis. Erythromycin may be used in children with penicillin allergy, but its efficacy is unproved. Prophylaxis in sickle cell disease has been safely discontinued after the 5th birthday in children who have received all recommended pneumococcal vaccine doses and who had not experienced invasive pneumococcal disease. Prophylaxis is often administered for at least 2 yr after splenectomy or up to 5 yr of age. Efficacy in children >5 yr of age and adolescents is unproved. If oral antibiotic prophylaxis is used, strict compliance must be encouraged. Given the rapid emergence of penicillin-resistant pneumococci, especially in children receiving long-term, low-dose therapy, prophylaxis cannot be relied on to prevent disease. High-risk children with fever should be promptly evaluated and treated regardless of vaccination history or penicillin prophylaxis.

Chapter 168 - Group A Streptococcus

Michael A. Gerber

Group A streptococcus, also known as *streptococcus pyogenes*, is a common cause of infections of the upper respiratory tract (pharyngotonsillitis) and the skin (impetigo, pyoderma) in children and is a less common cause of perianal cellulitis, vaginitis, septicemia, pneumonia, endocarditis, pericarditis, osteomyelitis, suppurative arthritis, myositis, cellulitis, and omphalitis. These microorganisms are also the cause of two distinct clinical entities, scarlet fever and erysipelas, as well as a toxic shock syndrome and necrotizing fasciitis. Group A streptococcus is also the cause of two potentially serious nonsuppurative complications, rheumatic fever (Chapter 168.1) and acute glomerulonephritis (Chapter 503.1).

Etiology.

Group A streptococci are gram-positive coccoid-shaped bacteria that tend to grow in chains. They are broadly classified by their reactions on mammalian red blood cells. The zone of complete hemolysis that surrounds colonies grown on blood agar distinguishes s-hemolytic (complete hemolysis) from a-hemolytic (green or partial hemolysis) and ? (nonhemolytic) species. The s-hemolytic streptococci can be divided into groups by a group-specific polysaccharide (Lancefield carbohydrate C) located in the cell wall. More than 20 serologic groups have been identified, designated by the letters A through T. Serologic grouping by the Lancefield method is precise, but group A organisms can be identified more readily by any one of a number of latex agglutination, coagglutination, or enzyme immunoassay procedures. Group A strains can also be distinguished from other groups by differences in sensitivity to bacitracin. A disc containing 0.04?U of bacitracin inhibits the growth of most group A strains, whereas other groups are generally resistant to this antibiotic.

Group A streptococcus can be subdivided into >80 serotypes on the basis of the **M protein** antigen, which is located on the cell surface and in fimbriae (hairlike fuzz) that project from the outer edge of the cell. M typing has relied primarily on the serologic typing of the surface M protein using available polyclonal sera. However, it is frequently difficult to detect M proteins in this way. Recently, a molecular approach to M typing group A streptococcal isolates was developed using the polymerase chain reaction technique and based on sequencing the *emm* gene of group A streptococcus that encodes the M protein. More than 100 distinct M types have been identified using *emm* typing, and there has been a good correlation between the

known serotypes and the *emm* types.

M serotyping has been valuable for epidemiologic studies; particular group A streptococcal diseases tend to be associated with certain M types. The M types commonly associated with pharyngitis rarely cause skin infections, and the M types commonly associated with skin infections rarely cause pharyngitis. A few of the "pharyngeal" strains (e.g., M type 12) have been associated with glomerulonephritis, but far more of the "skin" strains (e.g., M types 49, 55, 57, and 60) have been considered nephritogenic. A few of the "pharyngeal" serotypes, but none of the "skin" strains, have been associated with acute rheumatic fever. However, recent evidence suggests that rheumatogenic potential is not solely dependent on the serotype but is a characteristic of specific strains within several serotypes.

Epidemiology.

Humans are the natural reservoir for group A streptococcus. These bacteria are highly communicable and can cause disease in normal individuals of all ages who do not have type-specific immunity against the particular serotype involved. Disease in neonates is uncommon, probably because of maternally acquired antibody. The incidence of pharyngeal infections is highest in children >3 yr of age, especially in young school-aged children. These infections are most common in the northern regions of the United States, especially during winter and early spring. Children with untreated acute pharyngitis spread group A streptococcus by airborne salivary droplets and nasal discharge. Transmission is favored by close proximity, and, therefore, the school and the home are important environments for spread. The incubation period for pharyngitis is usually 2–5 days. Recent reports suggest that group A streptococcus has the potential to be an important upper respiratory tract pathogen and to produce outbreaks of disease in the daycare setting. Foods containing group A streptococcus occasionally cause explosive outbreaks of pharyngotonsillitis. Children are usually not infectious 24?hr after appropriate antibiotic therapy has been started. Chronic pharyngeal carriers of group A streptococcus rarely transmit this organism to others.

In contrast to upper respiratory tract infections, streptococcal pyoderma (impetigo) occurs most frequently during the summer in temperate climates, or year round in warmer climates, when the skin is exposed and abrasions and insect bites are more likely to occur. Colonization of healthy skin by group A streptococcus usually precedes the development of impetigo. The impetiguous lesions occur at the site of open lesions (e.g., insect bites, traumatic wounds, or burns) because group A streptococcus cannot penetrate intact skin. Spread is from skin to skin, not via the respiratory tract, although impetigo serotypes may colonize the throat. Fingernails and the perianal region can harbor group A streptococcus and play a role in disseminating impetigo. Multiple cases of impetigo in the same family are common. Both impetigo and pharyngitis are more likely to occur among children living in crowded homes and in poor hygienic circumstances.

The incidence of severe invasive group A streptococcal infections, including bacteremia, streptococcal toxic shock syndrome, and necrotizing fasciitis, has increased in recent years. The incidence appears to be highest in the very young and in older persons. Varicella is the most commonly identified risk factor in children. Other risk factors include diabetes mellitus, human immunodeficiency virus infection, intravenous drug use, and chronic pulmonary or chronic cardiac disease. The portal of entry is unknown in almost 50% of the cases of severe invasive group A streptococcal infection; in most cases, it is believed to be skin or mucous membrane. Severe invasive disease rarely follows group A streptococcal pharyngitis.

Pathogenesis.

Apart from its usefulness in typing, M protein has other important properties. Virulence of group A streptococcus depends primarily on the M protein, and strains rich in M protein resist phagocytosis in fresh human blood, whereas M-negative strains do not. Group A streptococcus isolated from chronic pharyngeal carriers contain little or no M protein and are relatively avirulent. The M protein antigen stimulates the production of protective antibodies. These antibodies are type-specific. They protect against infection with a homologous type but confer no immunity against other M types. Therefore, multiple group A streptococcal infections attributable to different types are common during childhood and adolescence. By adult life,

individuals are probably immune to many of the common types in the environment, but because of the large number of serotypes it is doubtful that total immunity is ever achieved.

Group A streptococcus produces a large variety of enzymes and toxins, including erythrogenic toxin (known as streptococcal pyrogenic exotoxin). Streptococcal pyrogenic exotoxins A, B, and C are responsible for the rash of scarlet fever and are elaborated by streptococci that are infected with a particular bacteriophage. These exotoxins stimulate the formation of specific antitoxin antibodies that provide immunity against the scarlatiniform rash but not against other streptococcal infections. However, because group A streptococcus can produce three different rash-producing pyrogenic exotoxins (A, B, or C), a second attack of scarlet fever can sometimes occur. Streptococcal pyrogenic exotoxins A, B, and C, as well as several newly discovered exotoxins, appear to be involved in the pathogenesis of invasive group A streptococcal disease, including the streptococcal toxic shock syndrome. In contrast to the streptococcal pyrogenic exotoxins, the roles of most of the streptococcal enzymes and toxins in human disease have yet to be established.

Many of the other extracellular substances are also antigenic and stimulate antibody production after an infection. However, these antibodies bear no relationship to immunity. Their measurement is useful for evidence of a recent streptococcal infection. The test for antibodies against streptolysin O (antistreptolysin O) is well standardized and is the most commonly used antibody determination. Because the immune response to extracellular antigens varies among individuals as well as with the site of infection, it is sometimes necessary to measure other streptococcal antibodies, such as anti-deoxyribonuclease (anti-DNase).

Clinical Manifestations.

The most common infections caused by group A streptococcus involve the

respiratory tract and the skin and soft tissues.

RESPIRATORY TRACT INFECTIONS.

Group A streptococcus is an important cause of acute pharyngitis (Chapter 366) and pneumonia (Chapter 389).

SCARLET FEVER.

Scarlet fever is an upper respiratory tract infection associated with a characteristic rash, which is caused by an infection with pyrogenic exotoxin (erythrogenic toxin)-producing group A streptococcus in individuals who do not have antitoxin antibodies. It is now encountered less commonly and is less virulent than in the past, but the incidence is cyclic, depending on the prevalence of toxin-producing strains and the immune status of the population. The modes of transmission, age distribution, and other epidemiologic features are otherwise similar to those for group A streptococcal pharyngitis.

The rash appears within 24–48?hr after onset of symptoms, although it may appear with the first signs of illness. It often begins around the neck and spreads over the trunk and extremities. It is a diffuse, finely papular, erythematous eruption producing a bright red discoloration of the skin, which blanches on pressure. It is often more intense along the creases of the elbows, axillae, and groin. The skin has a goose-pimple appearance and feels rough. The face is usually spared, although the cheeks may be erythematous with pallor around the mouth. After 3–4 days, the rash begins to fade and is followed by desquamation, first on the face, progressing downward, and often resembling that seen subsequent to a mild sunburn. Occasionally, sheetlike desquamation may occur around the free margins of the fingernails, the palms, and the soles. Examination of the pharynx of a patient with scarlet fever reveals essentially the same findings as with group A streptococcal pharyngitis. In addition, the tongue is usually coated and the papillae are swollen. After desquamation, the reddened papillae are prominent, giving the tongue a strawberry appearance.

Typical scarlet fever is not difficult to diagnose; however, the milder form with equivocal pharyngeal findings can be confused with rubella, roseola, Kawasaki disease, and drug eruptions. Staphylococcal infections are occasionally associated with a scarlatiniform rash. A history of recent exposure to a group A streptococcal infection is helpful. Identification of group A streptococcus in the pharynx confirms the diagnosis, if doubtful.

IMPETIGO.

Impetigo has traditionally been classified into two clinical forms: bullous and nonbullous (Chapter 655). Nonbullous impetigo is the more common form and is a superficial infection of the skin that appears first as a discrete papulovesicular lesion surrounded by a localized area of redness. The vesicles rapidly become purulent and covered with a thick, confluent, amber-colored crust that gives the appearance of having been stuck on the skin. The lesions may occur anywhere but are more common on the face and extremities. If untreated, nonbullous impetigo is a mild but chronic illness, often spreading to other parts of the body, but occasionally is self-limited. Regional lymphadenitis is common. Nonbullous impetigo is generally not accompanied by fever or other systemic signs or symptoms. Impetiginized excoriations around the nares are seen with active group A streptococcal infections of the nasopharynx. However, impetigo is not usually associated with an overt streptococcal infection of the upper respiratory tract.

Bullous impetigo is less common and occurs most often in neonates and young infants. It is characterized by flaccid, transparent bullae usually <3?cm in diameter on previously untraumatized skin. The usual distribution involves the face, buttocks, trunk, and perineum. Although *S. aureus* has traditionally been accepted as the sole pathogen responsible for bullous impetigo, there has been confusion about the organisms responsible for nonbullous impetigo. In most episodes of nonbullous impetigo, either group A streptococcus or *S. aureus*, or a combination of these two organisms, is isolated. Earlier investigations suggested that group A streptococcus was the causative agent in most cases of nonbullous impetigo and that *S. aureus* was only a secondary invader. However, studies performed over the past decade have demonstrated the emergence of *S. aureus*, either alone or in combination with group A streptococcus, as a causative agent in nonbullous impetigo. Culture of the lesions is the only way to distinguish nonbullous impetigo caused by *S. aureus* from that caused by group A streptococcus.

ERYSIPELAS.

Erysipelas is a relatively rare acute group A streptococcal infection involving the deeper layers of the skin and the underlying connective tissue. The skin over the affected area is swollen, red, and very tender. Superficial blebs may be present. The most characteristic finding is the sharply defined, slightly elevated border. At times, reddish streaks of lymphangitis project out from the margins of the lesion. A high fever and other systemic signs and symptoms of infection are present. Cultures obtained by needle aspirate of the inflamed area often reveal the causative agent.

PERIANAL DERMATITIS.

Perianal dermatitis, also called **perianal streptococcal disease**, is a distinct clinical entity characterized by well-demarcated, perianal erythema associated with anal pruritus, painful defecation, and blood-streaked stools. Physical examination reveals flat, pink to beefy-red perianal erythema with sharp margins extending as far as 2?cm from the anus. Erythema may involve the vulva and vagina. Lesions may be tender and, particularly when chronic, may fissure and bleed. Systemic symptoms and fever are unusual.

VAGINITIS.

Group A streptococcus is a common cause of vaginitis in prepubertal girls (Chapter 541). Patients usually have a serous discharge with marked erythema and irritation of the vulvar area, accompanied by discomfort in walking and in urination.

SEVERE INVASIVE DISEASE.

Invasive group A streptococcal infection is defined by isolation of group A

streptococcus from a normally sterile body site and includes three overlapping clinical syndromes. The first is group A streptococcal toxic shock syndrome, which is differentiated from other types of invasive group A streptococcal infections by the occurrence of shock and

multiorgan system failure early in the course of the infection (Box 168–1). The second is group A streptococcal necrotizing fasciitis characterized by extensive local necrosis of subcutaneous soft tissues and skin. The third is the group of focal and systemic infections that do not meet the criteria for toxic shock syndrome or necrotizing fasciitis and includes bacteremia with no identified focus, meningitis, pneumonia, peritonitis, puerperal sepsis, osteomyelitis, suppurative arthritis, myositis, and surgical wound infections.

The pathogenic mechanisms responsible for severe, invasive group A streptococcal infections, including streptococcal toxic shock syndrome and necrotizing fasciitis, have yet to be defined completely, but an association with streptococcal pyrogenic exotoxins has been suggested. The three original streptococcal pyrogenic exotoxins (A, B, and C), the newly discovered streptococcal pyrogenic exotoxins, and potentially other, as yet unidentified toxins produced by group A streptococcus, act as **superantigens**, which stimulate an intense activation and proliferation of T lymphocytes and macrophages resulting in the production of large quantities of cytokines. These cytokines are capable of producing shock and tissue injury, and are believed to be responsible for many of the clinical manifestations of severe, invasive group A streptococcal infections.

Diagnosis.

When attempting to decide whether to perform a microbiological test on a patient presenting with acute pharyngitis, consideration of the clinical and epidemiologic findings should take place before the test is performed. A history of close contact with a well-documented case of group A streptococcal pharyngitis is helpful, as is an awareness of a high prevalence of group A streptococcal infections in the community. Testing usually need not be performed on patients with acute pharyngitis whose clinical and epidemiologic features do not suggest a group A streptococcal etiology. However the signs and symptoms of streptococcal and nonstreptococcal pharyngitis overlap too broadly to allow the requisite diagnostic precision on clinical grounds alone. The clinical diagnosis of group A streptococcal pharyngitis cannot be made with certainty even by the most experienced physicians, and bacteriologic confirmation is required.

Culture of a throat swab on a sheep blood agar plate remains the standard for the documentation of the presence of group A streptococcus in the upper respiratory tract and for the confirmation of the clinical diagnosis of acute streptococcal pharyngitis. If performed correctly, a single throat swab cultured on a blood-agar plate has a sensitivity of 90–95% for detecting the presence of group A streptococcus in the pharynx.

A disadvantage of culturing a throat swab on a blood-agar plate is the delay (overnight or longer) in obtaining the culture result. Rapid antigen detection tests have been developed for the identification of group A streptococcus directly from throat swabs. Although these rapid tests are more expensive than the blood-agar culture, the advantage they offer over the traditional procedure is the speed with which they can provide results.

Box 168-1. Definition of Streptococcal Toxic Shock Syndrome

Hypotension plus two or more:

- Renal impairment
- Coagulopathy
- Hepatic involvement
- Adult respiratory distress syndrome
- Generalized erythematous macular rash
- Soft tissue necrosis

Definite case

- Clinical criteria plus group A streptococcus from a normally sterile site

Probable case

- Clinical criteria plus group A streptococcus from a nonsterile site

Rapid identification and treatment of patients with streptococcal pharyngitis can reduce the risk of the spread of group A streptococcus, allowing the patient to return to school or work sooner, and can reduce the acute morbidity of this illness.

The great majority of the rapid antigen detection tests that are currently available have an excellent specificity of >95% when compared with blood-agar plate cultures. False-positive test results are unusual, and, therefore, therapeutic decisions can be made on the basis of a positive test with confidence. Unfortunately, the sensitivity of most of these tests is 80–90%, possibly lower, when compared with the blood-agar plate culture. Newer tests may be more sensitive than other rapid antigen detection

tests and perhaps may even be as sensitive as blood-agar plate cultures. However, in view of conflicting data, physicians who elect to use any rapid antigen detection test in children and adolescents without culture backup of negative results should do so only after confirming in their own practice that the rapid test is comparable in sensitivity to the throat culture.

Group A streptococcal infection can also be diagnosed retrospectively on the basis of an elevated or increasing streptococcal antibody titer. The antistreptolysin O assay is the streptococcal antibody test most commonly used. Because streptolysin O also is produced by group C and G streptococcus, the test is not specific for group A infection. The antistreptolysin O response can be feeble in patients with streptococcal impetigo and its usefulness for this condition is limited. In contrast, the anti-DNase B responses are present after both skin and throat infections. A significant antibody increase is usually defined as an increase in titer of two or more dilution increments between the acute phase and convalescent phase specimens, regardless of the actual height of the antibody titer. A single antistreptolysin O titer is generally considered to be elevated if it is at least 240 Todd units in adults and 320 Todd units in children. Anti-DNase B titers of 240 Todd units or greater in school-aged patients, and 120 Todd units or greater in adults, are considered elevated. However, depending on the prevalence of group A streptococcal infections, a varying proportion of the population will show antistreptolysin O or anti-DNase B titers of this magnitude or even greater.

DIFFERENTIAL DIAGNOSIS.

Viruses are the most common cause of acute pharyngitis. Adenovirus, influenza virus, parainfluenza virus, rhinovirus, coxsackieviruses, ECHO viruses, herpes simplex virus, and respiratory syncytial virus frequently cause acute pharyngitis. Epstein-Barr virus is a frequent cause of acute pharyngitis that is often accompanied by the other clinical features of infectious mononucleosis (e.g., generalized lymphadenopathy, splenomegaly). Systemic infections with rubeola, cytomegalovirus, rubella, as well as a number of other viral agents may be associated with acute pharyngitis. Other agents such as *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* are uncommon causes of acute pharyngitis.

Although group A streptococcus is the most common cause of bacterial pharyngitis, other bacteria are also capable of producing acute pharyngitis. These include groups C and G ß-hemolytic streptococcus (Chapter 170) and *Corynebacterium diphtheriae* (Chapter 172). *Arcanobacterium haemolyticum* is a rare cause of acute pharyngitis that may be associated with a scarlet fever–like rash, particularly in teenagers. *Neisseria gonorrhoeae* can occasionally cause acute pharyngitis in sexually active individuals, and other bacteria such as *Francisella tularensis, Yersinia enterocolitica*, and mixed anaerobic infections (i.e., Vincent angina) are rare causes of acute pharyngitis.

Group A streptococcal pharyngitis is the only *commonly occurring* form of acute pharyngitis for which antibiotic therapy is definitely indicated. Therefore, when confronted with a patient with acute pharyngitis, the clinical decision that usually needs to be made is whether the pharyngitis is attributable to group A streptococcus.

Treatment.

Antibiotic therapy for patients with group A streptococcal pharyngitis can prevent acute rheumatic fever, shorten the clinical course of the illness, reduce transmission of the infection to others, and prevent suppurative complications. For the patient with classic scarlet fever, antibiotic therapy should be started immediately, but for the vast majority of patients who present with much less distinctive findings, treatment should be withheld until there is some form of bacteriologic confirmation either by throat culture or rapid antigen detection test. Rapid antigen detection tests, because of their high degree of specificity, have made it possible to initiate antibiotic therapy immediately for someone with a positive test result.

Group A streptococcus is exquisitely sensitive to penicillin, and resistant strains have never been encountered. Penicillin is, therefore, the drug of choice (except in patients who are allergic to penicillin) for pharyngeal infections as well as for suppurative complications. Treatment with oral penicillin V (250?mg/dose bid–tid PO) for 10 days is recommended but it must be taken for a full 10 days even though there is symptomatic improvement in 3–4 days. Penicillin V (phenoxyethylpenicillin) is preferred over penicillin G because it may be given without regard to mealtime. The major problem with all forms of oral therapy is the risk that the drug will be discontinued before the 10-day course has been completed. Therefore, when oral treatment is prescribed, the necessity of completing a full course of therapy must be emphasized. If the parents seem unlikely to comply because of family disorganization, difficulties in comprehension, or other reasons, parenteral therapy is indicated. A single intramuscular injection of benzathine penicillin G (600,000?IU for =60?lb, 1.2 million IU for >60?lb, IM) is the most efficacious and often the most practical method of treatment. Disadvantages include soreness around the site of injection, which may last for several days, and potential for injection into nerves or blood vessels if not administered correctly. The local reaction is diminished when benzathine penicillin G is combined in a single injection with procaine penicillin G, although precautions are necessary to ensure that an adequate amount of benzathine penicillin G is administered.

In some reports, as many as 20% of patients treated with a full course of penicillin continued to harbor group A streptococcus. The reasons for these bacteriologic failures are not clear. For patients who have received oral penicillin, poor compliance always has to be considered a possible explanation. It is likely that many of the failures of penicillin therapy occur in children who are merely group A streptococcal carriers. Therefore, routine follow-up throat cultures of asymptomatic patients who have completed a full course of therapy are not recommended.

Erythromycin (erythromycin estolate 20–40?mg/kg/24?hr divided bid–qid PO, or erythromycin ethylsuccinate 40?mg/kg/ 24?hr divided bid–qid PO) for 10 days is the drug of choice for patients allergic to penicillin. Although group A streptococcus that is resistant to erythromycin has rarely been encountered in the United States, erythromycin resistance has been a problem in other countries such as Japan and Finland.

A 10-day course of a narrow-spectrum oral cephalosporin is an acceptable alternative for patients allergic to penicillin. However, because up to 15% of penicillin-allergic patients are also cephalosporin-allergic, cephalosporins should not be given to patients with an immediate-type hypersensitivity to penicillin. The additional cost of cephalosporins and their broader spectrum of antibacterial activity compared with penicillin preclude their routine use in patients with group A streptococcal pharyngitis who are not penicillin-allergic. Sulfonamides and the tetracyclines are not indicated for treatment of group A streptococcal infections.

Most oral antibiotics must be administered for the conventional 10 days to achieve maximal pharyngeal eradication rates of group A streptococcus, but certain newer agents have been reported to achieve comparable bacteriologic and clinical cure rates when given for 5 days or less. Definitive results from comprehensive studies, however, are not available to allow final evaluation of these proposed shorter courses of oral antibiotic therapy. Therefore, they cannot be recommended at this time. In addition, these antibiotics have a much broader spectrum than penicillin, and most, even when administered for short courses, are more expensive.

Preliminary investigations have demonstrated that once daily amoxicillin therapy is effective in the treatment of group A streptococcal pharyngitis. If confirmed by additional investigations, once daily amoxicillin therapy, because of its low cost and relatively narrow spectrum, could become an alternative regimen for the treatment of group A streptococcal pharyngitis.

Antibiotic therapy for a patient with nonbullous impetigo can prevent local extension of the lesions, spread to distant infectious foci, and transmission of the infection to others. The ability of antibiotic therapy to prevent poststreptococcal glomerulonephritis, however, has not been clearly demonstrated. Patients with a few superficial, isolated lesions and no systemic signs can be treated with topical antibiotics. Mupirocin is a safe and effective agent that has become the topical treatment of choice. If there are widespread lesions or systemic signs, oral therapy with a ß-lactamase–resistant drug (e.g., dicloxacillin, cephalexin) will provide coverage for both group A streptococcus and *S. aureus*. Erythromycin is another alternative, particularly for those allergic to penicillin. However, rapidly emerging resistance to erythromycin among *S. aureus* in many areas suggests that it should not be used as first-line therapy.

Theoretical considerations and experimental data suggest that intravenous clindamycin is a more effective agent for the treatment of severe, invasive group A streptococcal infections than intravenous penicillin. However, because a small proportion of the group A streptococcal isolates in the United States are resistant to clindamycin, clindamycin should be used in combination with penicillin for these infections until susceptibility to clindamycin has been established. If necrotizing fasciitis is suspected, immediate surgical exploration or biopsy is required to identify a deep soft tissue infection that should be debrided immediately. Patients with streptococcal toxic shock syndrome require rapid and aggressive fluid replacement, management of respiratory or cardiac failure, if present, and anticipatory management of multiorgan system failure. Limited data suggest that intravenous gamma globulin is effective in the management of streptococcal toxic shock syndrome, but well-controlled studies have yet to be performed. Currently, intravenous immunoglobulin should be reserved for those patients who do not respond to other therapeutic measures.

Complications.

Suppurative complications from the spread of group A streptococcus to adjacent structures were very common before antibiotics became available. Cervical lymphadenitis, peritonsillar abscess, retropharyngeal abscess, otitis media, mastoiditis, and sinusitis still occur in children in whom the primary illness has gone unnoticed or in whom treatment of the pharyngitis has been inadequate. Group A streptococcal pneumonia can rarely occur.

Acute rheumatic fever (Chapter 168.1) and acute poststreptococcal glomerulonephritis (Chapter 503.1) are both nonsuppurative sequelae of infections with group A streptococcus that occur after an asymptomatic latent period. They are both characterized by lesions remote from the site of the group A streptococcal infection. However, acute rheumatic fever and acute glomerulonephritis differ in their clinical manifestations, epidemiology, and potential morbidity. In addition, acute glomerulonephritis can occur after a group A streptococcal infection of either the upper respiratory tract or the skin, but acute rheumatic fever can occur only after an infection of the upper respiratory tract.

POSTSTREPTOCOCCAL REACTIVE ARTHRITIS.

Poststreptococcal reactive arthritis has been used to describe a syndrome characterized by the onset of acute arthritis following an episode of group A streptococcal pharyngotonsillitis in a patient whose illness does not otherwise fulfill the Jones criteria for the diagnosis of acute rheumatic fever. There is still considerable debate about whether this entity represents a distinct syndrome or is a manifestation of acute rheumatic fever. Although poststreptococcal reactive arthritis usually involves the large joints, in contrast to the arthritis of acute rheumatic fever, it may involve small peripheral joints as well as the axial skeleton and is typically nonmigratory. The latent period between the antecedent episode of group A streptococcal pharyngitis and the poststreptococcal reactive arthritis is considerably shorter (usually <10 days) than that typically seen with acute rheumatic fever. In contrast to the arthritis of acute rheumatic fever, poststreptococcal reactive arthritis does not respond dramatically to therapy with aspirin or other nonsteroidal inflammatory agents. Even though no more than half of the patients with poststreptococcal reactive arthritis who have a throat culture performed have group A streptococcal isolated, all have serologic evidence of a recent group A streptococcal infection. It has been reported that a small proportion of patients with poststreptococcal reactive arthritis may go on to develop valvular heart disease. Therefore, these patients should be carefully observed for several months for the subsequent development of carditis. Some physicians administer secondary prophylaxis to these patients for a period of up to 1 yr. If carditis is not observed, the prophylaxis can then be discontinued. If carditis is detected, the patient should be classified as having had acute rheumatic fever and should continue to receive secondary prophylaxis.

PEDIATRIC AUTOIMMUNE NEUROPSYCHIATRIC DISORDERS ASSOCIATED WITH *STREPTOCOCCUS PYOGENES* (PANDAS).

PANDAS has been used to describe a group of neuropsychiatric disorders (particularly obsessive-compulsive disorders, tic disorders, and Tourette syndrome) for which a possible relationship with group A streptococcal infections has been suggested. It has been demonstrated that patients with Sydenham chorea (a form of acute rheumatic fever) frequently have obsessive-compulsive symptoms and that a subset of patients with obsessive-compulsive and tic disorders will have chorea as well as acute exacerbations following group A streptococcal infections. Therefore, it has been proposed that this subset of patients with obsessive-compulsive and tic disorders produce autoimmune antibodies in response to a group A streptococcal infection that cross-react with brain tissue similar to the autoimmune response believed to be responsible for the manifestations of Sydenham chorea. It has also been suggested that secondary prophylaxis that prevents recurrences of Sydenham chorea might also be effective in preventing recurrences of obsessive-compulsive and tic disorders in these patients. Because of the proposed autoimmune mechanism, it has also been suggested that these patients may benefit from immunoregulatory therapy such as plasma exchange or intravenous immunoglobulin therapy. The possibility that PANDAS could represent an extension of the spectrum of acute rheumatic fever is intriguing but is yet unproven. Until carefully designed and well-controlled studies have established a causal relationship between PANDAS and group A streptococcal infections, secondary prophylaxis to prevent, and immunoregulatory therapy to treat, PANDAS are not recommended.

Prognosis.

The prognosis for adequately treated group A streptococcal infections is excellent; most suppurative complications are prevented or readily treated. When therapy is provided promptly, acute rheumatic fever is prevented and complete recovery is the rule. However, there is no evidence that acute poststreptococcal glomerulonephritis can be prevented once pharyngitis or pyoderma with a nephritogenic strain of group A streptococcus has occurred. In rare instances, particularly in neonates or in children whose response to infection is compromised, fulminant pneumonia, septicemia, and death may occur despite usually adequate therapy.

Prevention.

The only specific indication for long-term use of antibiotics to prevent group A streptococcal infections is for patients with a history of acute rheumatic fever or rheumatic heart disease. Mass prophylaxis is generally not feasible except to reduce the number of infections during epidemics of impetigo and to control epidemics of pharyngitis in military populations and in schools.

Because the ability of antimicrobial agents to prevent group A streptococcal infections is limited, a streptococcal vaccine offers the possibility of a more effective approach. Investigators recently have purified and characterized M protein and have succeeded in separating M protein epitopes that evoke protective, type-specific antibodies from M protein epitopes that evoke heart cross-reactive antibodies. Moreover, chemically synthesized subpeptide fragments of M protein, copying known amino acid sequences of different M proteins, also have been found to be effective immunogens without evoking cross-reactive antibodies. Recent evidence suggests that protective antibodies can be produced to conserved, nontype-specific epitopes on the M protein that are shared by many different serologic types. Finally, work on new methods of vaccine delivery, such as intranasal administration, is being performed. An effective group A streptococcal vaccine that could be delivered by way of a mucosal route would have several advantages over parenteral vaccines, including cost, ease of delivery, and the production of protective secretory as well as serum antibodies.

Vaccine candidates have been developed using synthetic or recombinant peptide fragments derived from type-specific sequences of the M protein. Several multivalent, recombinant M protein vaccines have been constructed by placing protective peptide fragments of various M genes in tandem. When tested in rabbits using a parenteral route, a hexavalent M protein vaccine evoked opsonic antibodies with bactericidal activity against all six serotypes and no antibodies reactive with human heart tissue. Studies of this hexavalent vaccine in humans were recently initiated. Another vaccine candidate has been developed using a nonpathogenic commensal organism as a live vector to express a highly conserved region of the M protein that evokes a protective antibody response. Both IgA and IgG antibodies were produced in mice and rabbits following oral and intranasal administration of this vaccine candidate with no evidence of cross-reactive antibodies to human heart tissue. Investigations of this candidate vaccine in humans were recently initiated.

168.1 Rheumatic Fever

Etiology.

There is considerable evidence to support the link between group A streptococcus upper respiratory tract infections and acute rheumatic fever and rheumatic heart disease. As many as two thirds of the patients with an acute episode of rheumatic fever have a history of an upper respiratory tract infection several weeks before, and the peak age and seasonal incidence of acute rheumatic fever closely parallel those of group A streptococcal infections. Patients with acute rheumatic fever almost always have serologic evidence of a recent group A streptococcal infection. In addition, their antibody titers are usually considerably higher than those seen in patients with group A streptococcal infections without acute rheumatic fever. Outbreaks of group A streptococcal pharyngitis in closed communities, such as boarding schools or military bases, may be followed by outbreaks of acute rheumatic fever. Finally, antimicrobial therapy that eliminates group A streptococcus from the pharynx also prevents initial episodes of acute rheumatic fever,

and long-term, continuous prophylaxis that prevents group A streptococcal pharyngitis also prevents recurrences of acute rheumatic fever.

Not all of the serotypes of group A streptococcus can cause rheumatic fever. When some strains (e.g., M type 4) were present in a very susceptible rheumatic population, no recurrences of rheumatic fever occurred. In contrast, episodes of

pharyngitis with other serotypes prevalent in the same population were associated with frequent recurrences. The concept of rheumatogenicity is further supported by the observation that although serotypes of group A streptococcus frequently associated with skin infection are often isolated from the upper respiratory tract, they rarely cause recurrences of rheumatic fever in individuals with a previous history of rheumatic fever. In addition, certain serotypes of group A streptococcus (e.g., M types 1, 3, 5, 6, 18, 24) are more frequently isolated from patients with acute rheumatic fever than are other serotypes.

Epidemiology.

In some developing areas of the world, the annual incidence of acute rheumatic fever is currently as high as 282/100,000 population. Worldwide, rheumatic heart disease remains the most common form of acquired heart disease in all age groups, accounting for as much as 50% of all cardiovascular disease and as much as 50% of all cardiac admissions in many developing countries. However, striking differences are evident in the incidence of acute rheumatic fever and rheumatic heart disease among different ethnic groups within the same country; many, but not all, of these differences appear to be related to differences in socioeconomic status.

In the United States, at the beginning of the 20th century, acute rheumatic fever was the leading cause of death among children and adolescents, with annual incidence rates of 100–200/100,000 population. In addition, rheumatic heart disease was the leading cause of heart disease among adults <40 yr of age. At that time, as many as one fourth of the hospital beds in the United States were occupied by patients suffering from acute rheumatic fever or its complications. By the 1940s, the annual incidence of acute rheumatic fever had decreased to 50/100,000, and over the next 4 decades, the decline in incidence accelerated rapidly. By the early 1980s, the annual incidence in some areas of the United States was as low as 0.5/100,000 population. This sharp decline in the incidence of acute rheumatic fever has been observed in other industrialized countries as well.

The explanation for this dramatic decline in the incidence of acute rheumatic fever and rheumatic heart disease in the United States and other industrialized countries is not clear. Historically, acute rheumatic fever has been associated with poverty, particularly in urban areas. Much of the decline in the incidence of acute rheumatic fever in industrialized countries during the preantibiotic era can probably be attributed to improvements in living conditions. A number of studies have suggested that, of the various manifestations of poverty, crowding, which contributes to the spread of group A streptococcal infections, is the one most closely associated with the incidence of acute rheumatic fever. The decline in incidence of acute rheumatic fever in industrialized countries over the past 4 decades has also been attributable in large measure to the greater availability of medical care and to the widespread use of antibiotics. Antibiotic therapy of group A streptococcal pharyngitis has been important in preventing initial attacks and, particularly, recurrences of the disease. In addition, the decline can be attributed, at least in part, to a shift in the prevalent strains of group A streptococcus from rheumatogenic to nonrheumatogenic strains.

A dramatic outbreak of acute rheumatic fever in the Salt Lake City area began in early 1985, and 198 cases were reported by the end of 1989. Other outbreaks were reported between 1984 and 1988 in Columbus and Akron, OH; Pittsburgh, PA; Nashville and Memphis, TN; New York City, NY; Kansas City, MO; Dallas, TX; and among recruits at the San Diego Naval Training Center in California and at the Fort Leonard Wood Army Training Base in Missouri. Evidence suggests that this resurgence of acute rheumatic fever was focal and not nationwide.

Certain rheumatogenic serotypes (e.g., types 1, 3, 5, 6, and 18) that were isolated infrequently during the 1970s and early 1980s dramatically reappeared during these focal outbreaks. The appearance of these rheumatogenic strains in selected communities was probably a major factor in these outbreaks of acute rheumatic fever. Another property of group A streptococcus that has been associated with rheumatogenicity is the formation of highly mucoid colonies. Mucoid strains of group A streptococcus had only rarely been isolated from throat cultures in recent years. However, during these focal outbreaks of acute rheumatic fever, mucoid strains of group A streptococcus were commonly isolated from patients, family members, and members of the surrounding community.

In addition to the specific characteristics of the infecting group A streptococcus, the risk of a particular person developing acute rheumatic fever is also dependent upon various host factors. The incidence of both initial attacks and recurrences of acute rheumatic fever peaks in children aged 5–15 yr, the age of greatest risk for group A streptococcal pharyngitis. Patients who have had one attack of acute rheumatic fever tend to have recurrences, and the clinical features of the recurrences tend to mimic those of the initial attack. In addition, there appears to be a genetic predisposition to acute rheumatic fever. Studies in twins have shown a higher concordance rate of acute rheumatic fever in monozygotic than in dizygotic twin pairs. Recent investigations have also demonstrated an association between the presence of specific HLA markers and a B-cell alloantigen and susceptibility to acute rheumatic fever.

Pathogenesis.

The pathogenic link between a group A streptococcal infection of the upper respiratory tract and an attack of acute rheumatic fever, characterized by organ and tissue involvement far removed from the pharynx, is still not clear. One of the major obstacles to understanding the pathogenesis of acute rheumatic fever and rheumatic heart disease has been the inability to establish an animal model. Several theories of the pathogenesis of acute rheumatic fever and rheumatic heart disease have been proposed, but only two are seriously considered: the cytotoxicity theory and the immunologic theory.

The cytotoxicity theory suggests that a group A streptococcal toxin may be involved in the pathogenesis of acute rheumatic fever and rheumatic heart disease. Group A streptococcus produces several enzymes that are cytotoxic for mammalian cardiac cells. For example, streptolysin O has a direct cytotoxic effect on mammalian cells in tissue culture, and most of the proponents of the cytotoxicity theory have focused on this enzyme. However, one of the major problems with the cytotoxicity hypothesis is its inability to explain the latent period between an episode of group A streptococcal pharyngitis and the onset of acute rheumatic fever.

An immune-mediated pathogenesis for acute rheumatic fever and rheumatic heart disease has been suggested by the clinical similarity of acute rheumatic fever to other illnesses produced by immunopathogenic processes and by the latent period between the group A streptococcal infection and the acute rheumatic fever. The

antigenicity of a large variety of group A streptococcal products and constituents, as well as the immunologic cross-reactivity between group A streptococcal components and mammalian tissues, also lends support to this hypothesis. Common antigenic determinants are shared between certain components of group A streptococcus (e.g., M protein, protoplast membrane, cell wall group A carbohydrate, capsular hyaluronate) and specific mammalian tissues (e.g., heart, brain, joint). For example, certain M proteins (M1, M5, M6, and M19) share epitopes with human tropomyosin and myosin. Additionally, the involvement of group A streptococcal superantigens such as pyrogenic

exotoxins in the pathogenesis of acute rheumatic fever has been proposed.

Clinical Manifestations and Diagnosis.

Because no clinical or laboratory finding is pathognomonic for acute rheumatic fever, T. Duckett Jones in 1944 proposed guidelines to aid in diagnosis and to limit overdiagnosis. The Jones criteria, as revised in 1992 by the American Heart Association (Table 168–1 (Table Not Available)), are intended only for the diagnosis of the initial attack of acute rheumatic fever and not for recurrences. There are five major and four minor criteria and an absolute requirement for evidence (microbiologic or serologic) of recent group A streptococcal infection. The diagnosis of acute rheumatic fever can be established by the Jones criteria when a patient fulfills two major criteria or one major and two minor criteria and meets the absolute requirement. Even with strict application of the Jones criteria, overdiagnosis as well as underdiagnosis of acute rheumatic fever may occur. There are three circumstances in which the diagnosis of acute rheumatic fever can be made without strict adherence to the Jones criteria. Chorea may occur as the only manifestation of acute rheumatic fever. Similarly, indolent carditis may be the only manifestation in patients who first come to medical attention months after the onset of acute rheumatic fever. Finally, although most patients with recurrences of acute rheumatic fever fulfill the Jones criteria, some may not.

MAJOR MANIFESTATIONS.

There are five major criteria. The presence of two major criteria with evidence (microbiologic or serologic) of recent group A streptococcal infection fulfills the Jones criteria.

Migratory Polyarthritis. Arthritis occurs in about 75% of patients with acute rheumatic fever and typically involves larger joints, particularly the knees, ankles, wrists, and elbows. Involvement of the spine, small joints of the hands and feet, or hips is uncommon. Rheumatic joints are generally hot, red, swollen, and exquisitely tender; even the friction of bedclothes is uncomfortable. The pain can precede and can appear to be disproportionate to the other findings. The joint involvement is characteristically migratory in nature; a severely inflamed joint can become normal within 1–3 days without treatment, as one or more other large joints become involved. Severe arthritis can persist for several weeks in untreated patients. Monoarticular arthritis is unusual unless anti-inflammatory therapy is initiated prematurely, aborting the progression of the migratory polyarthritis. If a child with fever and arthritis is suspected of having acute rheumatic fever, it frequently is useful to withhold salicylates and observe for migratory progression. A dramatic response to even small doses of salicylates is another characteristic feature of the arthritis, and the absence of such a response should suggest an alternative diagnosis. Rheumatic arthritis is typically not deforming. Synovial fluid in acute rheumatic fever usually has 10,000–100,000 white blood cells/mm^3 with a predominance of neutrophils, a protein of about 4?g/dL, a normal

TABLE 168.1-1 -- **Guidelines for the Diagnosis of Initial Attack of Rheumatic Fever (Jones Criteria, Updated 1992)**

(Not Available)
Guidelines for the diagnosis of rheumatic fever: Jones criteria, updated 1992. JAMA 1992;268:2069–73. Copyright American Medical Association.

glucose, and forms a good mucin clot. Frequently, arthritis is the earliest manifestation of acute rheumatic fever and may correlate temporally with peak antistreptococcal antibody titers. There is an apparent inverse relationship between the severity of arthritis and the severity of cardiac involvement.

Carditis. Carditis and resultant chronic rheumatic heart disease are the most serious manifestations of acute rheumatic fever and account for essentially all of the associated morbidity and mortality. Rheumatic carditis is characterized by pancarditis, with active inflammation of myocardium, pericardium, and endocardium. Cardiac involvement during acute rheumatic fever varies in severity from fulminant, potentially fatal exudative pancarditis to mild, transient cardiac involvement. Endocarditis (valvulitis), which is manifest by one or more cardiac murmurs, is a universal finding in rheumatic carditis, whereas the presence of pericarditis or myocarditis is variable. Myocarditis and/or pericarditis without evidence of endocarditis is rarely due to rheumatic heart disease. Most cases consist of either isolated mitral valvular disease or combined aortic and mitral valvular disease. Isolated aortic or right-sided valvular involvement is uncommon. Serious and long-term illness is related entirely to valvular heart disease as a consequence of a single attack or recurrent attacks of acute rheumatic fever. Valvular insufficiency is characteristic of both acute and convalescent stages of acute rheumatic fever, whereas valvular stenosis usually appears several years or even decades after the acute illness. In developing countries, however, where acute rheumatic fever often occurs at a younger age, mitral stenosis and aortic stenosis may develop sooner after acute rheumatic fever than in developed countries, and can occur in young children.

Acute rheumatic carditis usually presents as tachycardia and cardiac murmurs, with or without evidence of myocardial or pericardial involvement. Moderate-to-severe rheumatic carditis can result in cardiomegaly and congestive heart failure with hepatomegaly and peripheral and pulmonary edema. Echocardiographic findings include pericardial effusion, decreased ventricular contractility, and aortic and/or mitral regurgitation. Mitral regurgitation is characterized by a high-pitched apical holosystolic murmur radiating to the axilla. In patients with significant mitral regurgitation, this may be associated with an apical mid-diastolic murmur of relative mitral stenosis. Aortic insufficiency is characterized by a high-pitched decrescendo diastolic murmur at the upper left sternal border. Echocardiographic demonstration of

valvular regurgitation without accompanying auscultatory evidence does not satisfy the Jones criteria for carditis.

Carditis occurs in about 50–60% of all cases of acute rheumatic fever. Recurrent attacks of acute rheumatic fever in patients who had carditis with the initial attack are associated with high rates of carditis. The major consequence of acute rheumatic carditis is chronic, progressive valvular disease, particularly

valvular stenosis, which can require valve replacement and predispose to infective endocarditis.

Chorea. Sydenham chorea occurs in about 10–15% of patients with acute rheumatic fever and usually presents as an isolated, frequently subtle, neurologic behavior disorder. Emotional lability, incoordination, poor school performance, uncontrollable movements, and facial grimacing, exacerbated by stress and disappearing with sleep, are characteristic. Chorea occasionally is unilateral. The latent period from acute group A streptococcal infection to chorea is usually longer than for arthritis or carditis and can be months. Onset can be insidious, with symptoms being present for several months before recognition. Clinical maneuvers to elicit features of chorea include (1) demonstration of milkmaid's grip (irregular contractions of the muscles of the hands while squeezing the examiner's fingers), (2) spooning and pronation of the hands when the patient's arms are extended, (3) wormian movements of the tongue upon protrusion, and (4) examination of handwriting to evaluate fine motor movements. Diagnosis is based on clinical findings with supportive evidence of group A streptococcal antibodies. However, in patients with a long latent period from the inciting streptococcal infection, antibody levels may have declined to normal. Although the acute illness is distressing, chorea rarely if ever leads to permanent neurologic sequelae.

Erythema Marginatum. Erythema marginatum is a rare (<3% of patients with acute rheumatic fever) but characteristic rash of acute rheumatic fever. It consists of erythematous, serpiginous, macular lesions with pale centers that are not pruritic. It occurs primarily on the trunk and extremities, but not on the face, and it can be accentuated by warming the skin.

Subcutaneous Nodules. Subcutaneous nodules are a rare (=1% of patients with acute rheumatic fever) and consist of firm nodules approximately 1?cm in diameter along the extensor surfaces of tendons near bony prominences. There is a correlation between the presence of these nodules and significant rheumatic heart disease.

MINOR MANIFESTATIONS.

The two clinical minor manifestations are arthralgia (in the absence of polyarthritis as a major criterion) and fever (typically temperature =102℉ and occurring early in the course of illness). The two laboratory minor manifestations are elevated acute-phase reactants (e.g., C-reactive protein, erythrocyte sedimentation rate) and prolonged PR interval on electrocardiogram (first-degree heart block). However, a prolonged PR interval alone does not constitute evidence of carditis or predict long-term cardiac sequelae.

RECENT GROUP A STREPTOCOCCUS INFECTION.

An absolute requirement for the diagnosis of acute rheumatic fever is supporting evidence of a recent group A streptococcal infection. Acute rheumatic fever typically develops 2–4 wk after an acute episode of group A streptococcal pharyngitis at a time when clinical findings of pharyngitis are no longer present and when only 10–20% of the throat culture or rapid streptococcal antigen test results are positive. One third of patients have no history of an antecedent pharyngitis. Therefore, evidence of an antecedent group A streptococcal infection is usually based on elevated or increasing serum antistreptococcal antibody titers. A slide agglutination test (Streptozyme) has been introduced, and it is purported to detect antibodies against five different group A streptococcal antigens. Although this test is rapid, relatively simple to perform, and widely available, it is less standardized and less reproducible than other tests and should not be used as a diagnostic test for evidence of an antecedent group A streptococcal infection. If only a single antibody is measured (usually antistreptolysin O), only 80–85% of patients with acute rheumatic fever have an elevated titer; however, 95–100% have an elevation if three different antibodies (antistreptolysin O, anti-DNase B, antihyaluronidase) are measured. Therefore, when acute rheumatic fever is suspected clinically, multiple antibody tests are performed. Except for patients with chorea, clinical findings of acute rheumatic fever generally coincide with peak antistreptococcal antibody responses. Most patients with chorea have elevation of antibodies to one or more group A streptococcal antigens, although these antibodies may be waning. The diagnosis of acute rheumatic fever should not be made in patients with elevated or increasing streptococcal antibody titers who do not fulfill the Jones criteria because such titer changes may be coincidental. This is most often true in younger, school-aged children, many of whom have group A streptococcal pyoderma in the summer or unrelated group A streptococcal pharyngitis during the winter and spring months.

DIFFERENTIAL DIAGNOSIS.

The differential diagnoses of rheumatic fever include many infectious as well as noninfectious illnesses (Table 168–2). When children present with arthritis, a collagen vascular disease must be considered. Rheumatoid arthritis in particular must be distinguished from acute rheumatic fever. Children with rheumatoid arthritis tend to be younger and usually have less joint pain relative to their other clinical findings than those with acute rheumatic fever. Spiking fevers, lymphadenopathy, and splenomegaly are more suggestive of rheumatoid arthritis than acute rheumatic fever. The response to salicylate therapy is also much less dramatic with rheumatoid arthritis than with acute rheumatic fever. Systemic lupus erythematosus can usually be distinguished from acute rheumatic fever on the basis of the presence of antinuclear antibodies with systemic lupus erythematosus. Other causes of arthritis, such as gonococcal arthritis, malignancies, serum sickness, Lyme disease, sickle cell disease, and reactive arthritis related to gastrointestinal infections (e.g., *Shigella, Salmonella, Yersinia)* should also be considered.

When carditis is the sole major manifestation of suspected acute rheumatic fever,

viral myocarditis, viral pericarditis, Kawasaki disease, and infective endocarditis should also be considered. Patients with infective endocarditis may present with both joint and cardiac manifestations. These patients can usually be distinguished from patients with acute rheumatic fever by blood cultures and the presence of associated findings (e.g., hematuria, splenomegaly, splinter hemorrhages). In general, the absence of auscultatory evidence of a significant cardiac murmur excludes the diagnosis of acute rheumatic carditis.

When chorea is the sole major manifestation of suspected acute rheumatic fever, Huntington chorea, Wilson disease, systemic lupus erythematosus, and various encephalitides should also be considered. These other diseases are usually identified by the history, laboratory studies, and clinical findings.

Treatment.

All patients with acute rheumatic fever should be placed on bed rest and monitored closely for evidence of carditis. They can be allowed to ambulate as soon as the signs of acute inflammation have subsided. However, patients with carditis require longer periods of bed rest.

ANTIBIOTIC THERAPY.

Once the diagnosis of acute rheumatic fever has been established and regardless of the throat

TABLE 168.1-2 -- **Differential Diagnosis of Acute Rheumatic Fever**

Arthritis	Carditis	Chorea
Rheumatoid arthritis	Viral myocarditis	Huntington chorea
Reactive arthritis (e.g., *Shigella, Salmonella, Yersinia*)	Viral pericarditis	Wilson disease
Serum sickness	Infective endocarditis	Systemic lupus erythematosus
Sickle cell disease	Kawasaki disease	Cerebral palsy
Malignancies	Congenital heart disease	Tics
Systemic lupus erythematosus	Mitral valve prolapse	Hyperactivity
Lyme disease	Innocent murmurs	
Gonococcal infection		

culture results, the patient should receive 10 days of orally administered penicillin or erythromycin, or a single intramuscular injection of benzathine penicillin to eradicate group A streptococcus from the upper respiratory tract. After this initial course of antibiotic therapy, the patient should be started on long-term antibiotic prophylaxis.

ANTI-INFLAMMATORY THERAPY.

Anti-inflammatory agents (e.g., salicylates, corticosteroids) should be withheld if arthralgia or atypical arthritis is the only clinical manifestation of presumed acute rheumatic fever. Premature treatment with one of these agents may interfere with the development of the characteristic migratory polyarthritis and thus obscure the diagnosis of acute rheumatic fever. Agents such as acetaminophen can be used to control pain and fever while the patient is being observed for more definite signs of acute rheumatic fever or for evidence of another disease.

Patients with typical migratory polyarthritis and those with carditis without cardiomegaly or congestive heart failure should be treated with oral salicylates. The usual dose of aspirin is 100?mg/kg/24?hr divided qid PO for 3–5 days, followed by 75?mg/kg/24?hr divided qid PO for 4 wk. Determination of the serum salicylate level is not necessary unless the arthritis does not respond or signs of salicylate toxicity (e.g., tinnitus, hyperventilation) develop. There is no evidence that nonsteroidal anti-inflammatory agents are any more effective than salicylates.

Patients with carditis and cardiomegaly or congestive heart failure should receive corticosteroids. The usual dose of prednisone is 2?mg/kg/24?hr in 4 divided doses for 2–3 wk followed by a tapering of the dose that reduces the dose by 5?mg/24?hr every 2–3 days. At the beginning of the tapering of the prednisone dose, aspirin should be started at 75?mg/kg/24?hr in 4 divided doses for 6 wk. Supportive therapies for patients with moderate-to-severe carditis include digoxin, fluid and salt restriction, diuretics, and oxygen. The cardiac toxicity of digoxin is enhanced with myocarditis.

Termination of the anti-inflammatory therapy may be followed by the reappearance of clinical manifestations or of laboratory abnormalities. These “rebounds” are best left untreated unless the clinical manifestations are severe; salicylates or steroids should be reinstated in such cases.

SYDENHAM CHOREA.

Because chorea often occurs as an isolated manifestation after the resolution of the acute phase of the disease, anti-inflammatory agents are usually not indicated.

Sedatives may be helpful early in the course of chorea; phenobarbital (16–32?mg q 6–8?hr PO) is the drug of choice. If phenobarbital is ineffective, then haloperidol (0.01–0.03?mg/kg/ 24?hr divided bid PO) or chlorpromazine (0.5?mg/kg q 4–6?hr PO) should be initiated.

Complications.

The arthritis and chorea of acute rheumatic fever resolve completely without sequelae. Therefore, the long-term sequelae of rheumatic fever are usually limited to the heart.

Patients with cardiac valvular disease secondary to acute rheumatic fever are at increased risk of developing infective endocarditis during episodes of transient bacteremia. The antibiotic regimens used to prevent recurrences of acute rheumatic fever are inadequate for protection against infective endocarditis. Therefore, these patients require short-term antibiotic prophylaxis before surgical or dental procedures that are associated with transient bacteremia. The current recommendations of the American Heart Association regarding infective endocarditis prophylaxis should be followed (Chapter 429). The importance of good dental hygiene in the prevention of infective endocarditis should also be stressed. Patients who have had rheumatic fever but have no evidence of residual valvular disease do not require endocarditis prophylaxis.

Prognosis.

The prognosis for patients with acute rheumatic fever depends on the clinical manifestations present at the time of the initial episode, the severity of the initial episode, and the presence of recurrences. Approximately 70% of the patients with carditis during the initial episode of acute rheumatic fever recover with no residual heart disease; the more severe the initial cardiac involvement, the greater the risk of residual heart disease. Patients without carditis during the initial episode are unlikely to have carditis with recurrences. In contrast, patients with carditis during the initial episode are likely to have carditis with recurrences, and the risk of permanent heart damage increases with each recurrence. Patients who have had acute rheumatic fever are susceptible to recurrent attacks following reinfection of the upper respiratory tract with group A streptococcus. Therefore, these patients require long-term continuous chemoprophylaxis.

Before antibiotic prophylaxis was available, 75% of patients who had an initial episode of acute rheumatic fever had one or more recurrences during their lifetime. These recurrences were a major source of morbidity and mortality. The risk of recurrence is highest immediately after the initial episode and decreases with time.

Approximately 20% of patients who present with “pure” chorea who are not put on secondary prophylaxis develop rheumatic heart disease within 20 yr. Therefore, patients with chorea, even in the absence of other manifestations of rheumatic fever, require long-term antibiotic prophylaxis.

Prevention.

Prevention of both initial and recurrent episodes of acute rheumatic fever depends on controlling group A streptococcal infections of the upper respiratory tract. Prevention of initial attacks (primary prevention) depends on identification and eradication of the group A streptococcus that produces episodes of acute pharyngitis. Individuals who have already suffered an attack of acute rheumatic fever are particularly susceptible to recurrences of rheumatic fever with any subsequent group A streptococcus upper respiratory tract infection, whether or not they are symptomatic. Therefore, these patients should receive continuous antibiotic prophylaxis to prevent recurrences (secondary prevention).

PRIMARY PREVENTION.

Appropriate antibiotic therapy instituted before the 9th day of symptoms of acute group A streptococcal pharyngitis is highly effective in preventing first attacks of acute rheumatic fever from that episode. However, about one third of patients with acute rheumatic fever do not recall a preceding episode of pharyngitis.

SECONDARY PREVENTION.

Secondary prevention is directed at preventing acute group A streptococcal pharyngitis in patients at substantial risk of recurrent acute rheumatic fever. Secondary prevention requires continuous antibiotic prophylaxis, which should begin as soon as the diagnosis of acute rheumatic fever has been made and immediately after a full course of antibiotic therapy has been completed. Because patients who have had carditis with their initial episode of acute rheumatic fever are at a relatively high risk of having carditis with recurrences and of sustaining additional cardiac damage, they should receive antibiotic prophylaxis well into adulthood and perhaps for life.

Patients who did not have carditis with their initial episode of acute rheumatic fever have a relatively low risk of carditis with recurrences. Antibiotic prophylaxis may be discontinued in these patients when they reach their early 20s and after at least 5 yr have elapsed since their last episode of acute rheumatic fever. The decision to discontinue prophylactic antibiotics should be made only after careful consideration of potential risks and benefits and of epidemiologic factors such as the risk of exposure to group A streptococcal infections.

The regimen of choice for secondary prevention is a single intramuscular injection of benzathine penicillin G (1.2 million IU) every 4 wk (Table 168–3 (Table Not Available)). In certain high-risk patients, and in certain areas of the world where the incidence of rheumatic fever is particularly high, use of benzathine penicillin G every 3 wk may be necessary because levels of penicillin may decrease to marginally effective amounts after 3 wk. In compliant patients, continuous oral antimicrobial prophylaxis can be

TABLE 168.1-3 -- **Secondary Prevention of Rheumatic Fever**

(Not Available)

used. Penicillin V given twice daily and sulfadiazine given once daily are equally effective when used in such patients. For the exceptional patient who is allergic to both penicillin and sulfonamides, erythromycin given twice daily may be used.

Chapter 169 - Group B Streptococcus

Catherine S. Lachenauer
Michael R. Wessels

Group B streptococcus (GBS), or *Streptococcus agalactiae*, has been recognized as a major cause of neonatal bacterial sepsis in the United States since the 1960s. While advances in prevention strategies have led to a recent decline in the incidence of neonatal disease, GBS remains a major pathogen for neonates, pregnant women, and immunocompromised nonpregnant adults.

Etiology.

Group B streptococci are facultative anaerobic gram-positive cocci that form chains or diplococci in broth and small gray-white colonies on solid medium. GBS is definitively identified by demonstration of the Lancefield group B carbohydrate antigen, such as with latex agglutination techniques widely used in clinical laboratories. Presumptive identification can be established on the basis of a narrow zone of ß-hemolysis on blood agar, resistance to bacitracin and trimethoprim-sulfamethoxazole, lack of hydrolysis of bile esculin, and elaboration of cAMP factor (cyclic adenosine monophosphate, an extracellular protein that, in the presence of the beta toxin of *Staphylococcus aureus*, produces a zone of enhanced hemolysis on sheep's blood agar). Individual GBS strains are serologically classified according to the presence of one of the structurally distinct capsular polysaccharides (CPS), which are important virulence factors and stimulators of antibody-associated immunity. To date, nine CPS types have been identified: types Ia, Ib, II, III, IV, V, VI, VII, and VIII.

Epidemiology.

GBS emerged as a prominent neonatal pathogen in the late 1960s. For the next 2 decades, the incidence of neonatal GBS disease remained fairly constant, affecting 1–5.4/ 1,000 liveborn infants in the United States. Two patterns of disease were seen: early onset disease, which presents <7 days of age, and late-onset disease, which presents at 7 days of age or later. In the 1990s, widespread implementation of maternal chemoprophylaxis led to a striking 65% decrease in the incidence of early onset neonatal GBS disease in the United States, from 1.7/1,000 live births to 0.6/1,000 live births, whereas the incidence of late-onset disease remained essentially stable at approximately 0.4/1,000 (Fig. 169–1 (Figure Not Available)). In other developed countries, rates of neonatal GBS disease are similar to those in the United States during the prechemoprophylaxis era. In the developing world, GBS is not a major cause of neonatal sepsis, even though the prevalence of maternal vaginal colonization with GBS (a major risk factor for neonatal disease) among women from developing countries is similar to that reported among women living in the United States. The incidence of neonatal GBS disease is higher in premature and low-birthweight infants, although most cases occur in full-term infants.

Figure 169-1 (Figure Not Available) Incidence of early onset and late-onset invasive group B streptococcus disease in three active surveillance areas (California, Georgia, and Tennessee), 1989 through 2000, and activities for the prevention of group B streptococcus disease. Arrows designate the dates when prevention activities occurred. ACOG, American College of Obstetricians and Gynecologists; AAP, American Academy of Pediatrics. (Adapted from Centers for Disease Control and Prevention: Early-onset group B streptococcal disease—United States, 1998–1999. *MMWR Morb Mortal Wkly Rep* 2000;49:793–6; and Schrag SJ, Zywicki S, Farley MM, et al: Group B streptococcal disease in the era of intrapartum antibiotic prophylaxis. *N Engl J Med* 2000;342:15–20.)

Colonization by GBS in healthy adults is common. Vaginal or rectal colonization occurs in up to approximately 30% of pregnant women and is the usual source for GBS transmission to newborn infants. In the absence of maternal chemoprophylaxis, approximately 50% of infants born to colonized women acquire GBS colonization, and 1–2% of these infants develop invasive disease. Heavy maternal colonization increases the risk of infant colonization and development of early onset disease. Additional risk factors for early onset disease include prolonged rupture of membranes, intrapartum fever, prematurity, maternal bacteriuria during pregnancy, or previous delivery of an infant who developed GBS disease. Risk factors for late onset disease are less well-defined. Whereas late-onset disease may follow vertical transmission, horizontal acquisition from nursery sources also has been described.

GBS is also an important cause of invasive disease in adults. GBS may cause urinary tract infections, bacteremia, endometritis, chorioamnionitis, and wound infection in pregnant and parturient women. In nonpregnant adults with underlying medical conditions such as diabetes mellitus, cirrhosis, or malignancy, GBS may cause serious infections such as bacteremia, skin and soft tissue infections, endocarditis, pneumonia, and meningitis. In the era of maternal chemoprophylaxis, 78% of invasive GBS infections occur in nonpregnant adults.

The serotypes most commonly associated with neonatal GBS disease are types Ia, III, V, Ib, and II. Strains of serotype III are isolated in up to 80–90% of late-onset disease and of meningitis associated with early or late-onset disease. The serotype distribution of colonizing and invasive strains from pregnant women is similar to that from infected newborns. In Japan, serotypes VI and VIII have been reported as common maternal colonizing serotypes, and case reports indicate that type VIII strains may cause neonatal disease indistinguishable from that caused by other serotypes.

Pathogenesis.

A major risk factor for the development of early onset neonatal GBS infection is

maternal vaginal or rectal colonization by GBS. Infants acquire GBS during passage through the birth canal or, in some cases, via ascending infection. Fetal aspiration of infected amniotic fluid may occur. The incidence of early onset GBS infection increases with the length of rupture of membranes. Infection may also occur through seemingly intact membranes. In cases of late-onset infection, GBS may be vertically transmitted or acquired later from maternal or nonmaternal sources.

Several bacterial factors are implicated in the pathophysiology of invasive GBS disease. Foremost among these is the type-specific capsular polysaccharide. In animals, highly virulent GBS strains elaborate more capsular polysaccharide than do avirulent strains, and, in humans, strains associated with invasive disease elaborate more capsular polysaccharide than do colonizing isolates. All GBS capsular polysaccharides are high molecular weight polymers containing at least three of the following four sugars: glucose, galactose, N-acetylglucosamine, and rhamnose. All contain a short side chain terminating in N-acetylneuraminic acid (sialic acid). Studies in type III GBS show that the sialic acid component of the capsular polysaccharide prevents activation of the alternative complement pathway in the absence of type-specific antibody. Thus, the capsular polysaccharide appears to exert a virulence effect by protecting the organism from opsonophagocytosis in the nonimmune host. In addition, type-specific virulence attributes are suggested by the fact that type III strains are implicated in most cases of late-onset neonatal GBS disease and meningitis. Type III strains are taken up by brain endothelial cells more efficiently in vitro than strains of other serotypes, although studies using acapsular mutant strains demonstrate that it is not the capsule itself that facilitates cellular invasion. Other putative GBS virulence factors include GBS surface proteins, which may play a role in adhesion to host cells; C5a peptidase, which is postulated to inhibit the recruitment of polymorphonuclear cells into sites of infection; beta hemolysin, which has been associated with cell injury in vitro studies; and hyaluronidase, which has been postulated to act as a spreading factor in host tissues.

Mothers colonized with type III GBS who give birth to healthy infants had higher levels of capsular polysaccharide-specific antibody than women who give birth to infants who developed invasive disease. In addition, there is a high correlation of antibody to type III CPS in mother-infant paired sera. Together, these observations indicate that transplacental transfer of maternal antibody is critically involved in neonatal immunity to GBS. Optimal immunity to GBS also requires an intact complement system. Animal studies using C3- and C4-deficient mice demonstrate that the classic complement pathway is an important component of GBS immunity in the absence of specific antibody, but that antibody-mediated opsonophagocytosis may proceed via the alternative complement pathway. These and other results indicate that anticapsular antibody can overcome the prevention of C3 deposition on the bacterial surface by the sialic acid component of the type III capsule.

The precise steps between GBS colonization and invasive disease remain unclear. In vitro studies showing GBS entry of alveolar epithelium and pulmonary vasculature endothelial cells suggest that GBS may gain access to the bloodstream via invasion from the alveolar space, perhaps following intrapartum aspiration of infected fluid. However, highly encapsulated GBS strains enter eukaryotic cells poorly in vitro compared with capsule-deficient organism, yet they are associated with virulence clinically and in experimental infection models. Additional investigation is needed to define the contribution of GBS entry into host cells in the pathogenesis of GBS infection.

In in vitro and in animal models, GBS induces the release of proinflammatory cytokines. The group B antigen and the peptidoglycan component of the GBS cell wall are potent inducers of tumor necrosis factor (TNF)-a release in vitro, whereas purified type III capsular polysaccharide is not. Wild-type and isogenic unencapsulated mutant GBS strains induced similar amounts of interleukin (IL)-6 or TNF-a in vitro and similar changes in pulmonary vascular resistance and blood gas abnormalities in animals. Thus, it appears that, even though the capsule plays a central role in virulence through avoidance of immune clearance, the capsule does not directly contribute to cytokine release and the resultant inflammatory response.

Clinical Manifestations.

Two syndromes of neonatal GBS disease are distinguishable on the basis of age at presentation, epidemiologic characteristics, and clinical features (Table 169–1 (Table Not Available)). **Early onset neonatal GBS disease** presents within the first 7 days of life and is often associated with maternal obstetric complications, including chorioamnionitis, prolonged rupture of membranes, and premature labor. Infants may appear ill at the time of delivery, and most infants become ill within the first 24 hours of birth. In utero infection may result in septic abortion. The most common manifestations of early onset GBS disease are sepsis (50%), pneumonia (30%), and meningitis (15%). Asymptomatic bacteremia is uncommon but can occur. In symptomatic patients, nonspecific signs such as fever, irritability, lethargy, apnea, and bradycardia may be present. Respiratory symptoms are prominent regardless of the presence of pneumonia and include cyanosis, apnea, tachypnea, grunting, flaring, and retractions. A fulminant course with hemodynamic abnormalities including tachycardia, acidosis, and shock may ensue. Persistent fetal circulation may develop. Clinically and radiographically, pneumonia associated with early onset GBS disease is difficult to distinguish from hyaline membrane disease. Patients with meningitis often present with nonspecific findings, with more specific signs of CNS involvement initially being absent.

881

TABLE 169-1 -- **Characteristics of Early and Late Onset GBS Disease**

(Not Available)
Adapted from Schrag SJ, Zywicki S, Farley MM, et al: Group B streptococcal isease in the era of intrapartum antibiotic prophylaxis.N Engl J Med 2000;342:15–20.

Late onset neonatal GBS disease occurs on or after 7 days of life and most commonly manifests as bacteremia (45–60%) and meningitis (25–35%). Focal infections involving bone and joints, skin and soft tissue, the urinary tract, or lungs have been reported in approximately 20% of patients with late-onset disease. Cellulitis and adenitis are often localized to the submandibular or parotid regions. In contrast to early onset disease, maternal obstetric complications are not risk factors for the development of late-onset GBS disease. Infants with late-onset disease are

often less severely ill on presentation than infants with early onset disease and the disease is often less fulminant.

Invasive GBS disease in children beyond early infancy is uncommon. In a multistate surveillance study in the 1990s, 2% of all cases of invasive GBS disease were identified in children age 90 days to 14 yr. Two of the more common syndromes associated with childhood GBS disease beyond early infancy are bacteremia and endocarditis. HIV infection should be considered in children with invasive GBS disease beyond the neonatal period.

Diagnosis.

A major challenge is distinguishing between hyaline membrane disease and invasive neonatal GBS infection, because the two illnesses share clinical and radiographic features. Severe apnea, early onset of shock, abnormalities in the peripheral leukocyte count, and greater lung compliance may be more likely in infants with GBS disease. Other neonatal pathogens, such as *Escherichia coli* or *Listeria monocytogenes*, may produce illness that is clinically indistinguishable from that due to GBS.

The diagnosis of invasive GBS disease is established by isolation and identification of the organism from a normally sterile site, such as blood, urine, or cerebrospinal fluid (CSF). Isolation of GBS from gastric or tracheal aspirates or from skin or mucous membranes indicates colonization and is not diagnostic of invasive disease. CSF should be examined in all neonates suspected of having sepsis, because specific CNS signs are often absent in the presence of meningitis, especially in early onset disease. Antigen detection methods that use group B polysaccharide-specific antiserum, such as latex particle agglutination, are available for testing of urine, blood, and CSF, but these tests are less sensitive than culture. Moreover, antigen is often detected in urine samples collected by bag from otherwise healthy neonates who are colonized with GBS on the perineum or rectum.

Laboratory Findings.

Frequently present are abnormalities in the peripheral white blood cell count, including an increased or decreased absolute neutrophil count, an elevated band count, an elevated ratio of bands to total neutrophils, or leukopenia. Elevations in the C-reactive protein level have been investigated as a potential early marker of GBS sepsis but appear unreliable. Findings on chest radiograph are often indistinguishable from those of hyaline membrane disease and may include reticulogranular patterns, patchy infiltrates, generalized opacification, pleural effusions, or increased interstitial markings.

Treatment.

Penicillin G is the treatment of choice of confirmed GBS infection. Initial therapy of neonatal sepsis should include ampicillin and an aminoglycoside, both for the need for broad coverage pending organism identification and for synergistic bactericidal activity. Therapy may be completed with penicillin alone, once GBS has been definitively identified and a good clinical response has occurred. Especially in cases of meningitis, high doses of penicillin (450,000–500,000?U/kg/24?hr) and ampicillin are recommended (300–400?mg/kg/24?hr) because of the relatively high mean inhibitory concentration of penicillin for GBS as well as the potential for a high initial CSF inoculum. Duration of therapy varies according to the site of infection (Table 169–2) and should be guided by clinical circumstances.

In cases of GBS meningitis, some experts recommend that additional CSF be sampled within 24–48?hr to determine whether sterility has been achieved. Persistent GBS growth may indicate an unsuspected intracranial focus or an insufficient antibiotic dose.

Because antibody directed to the capsular polysaccharide has been demonstrated to be protective against GBS infection, administration of intravenous immunoglobulin (IVIG) has been investigated as an adjunctive therapy for neonatal GBS infection. Administration of standard IVIG appears to be safe and well-tolerated, but not clearly of benefit in infants with GBS infection. This may reflect variable and often low concentrations of GBS capsular-specific IgG in normal adults. Attempts have been made at providing large amounts of opsonically active antibody to infants through the use of hyperimmune serum produced by immunizing donors with a GBS vaccine, but to date clinical trials large enough to demonstrate efficacy of hyperimmune IVIG have not been performed.

For recurrent neonatal GBS disease, standard intravenous antibiotic therapy followed by attempted eradication of GBS mucosal colonization has been suggested. This is based on the findings in several studies that invasive isolates from recurrent episodes are often identical to each other and to colonizing strains from the affected infant. Rifampin has most frequently been used for this purpose, but a recent report demonstrates that eradication of GBS colonization in infants is not reliably achieved by rifampin therapy. Optimal management of this uncommon situation remains unclear.

Prognosis.

Studies from the 1970s and 1980s showed that up to 30% of infants surviving GBS meningitis had major long-term neurologic sequelae, including developmental delay, spastic quadriplegia, microcephaly, seizure disorder, cortical blindness, or deafness; less severe neurologic complications may be present in other survivors. More contemporary data are not available. Periventricular leukomalacia and severe developmental delay may result from GBS disease and accompanying shock in premature infants, even in the absence of meningitis. The outcome of focal GBS infections outside of the central nervous system, such as bone or soft tissue infections, is generally favorable.

In the 1990s, the case fatality rates associated with early and late-onset neonatal GBS disease were 4.7% and 2.8%, respectively. Mortality is higher in premature infants; one study reported a case fatality rate of 30% in infants whose gestational

TABLE 169-2 -- **Recommended Duration of Therapy for Manifestations of GBS Disease**

Treatment	Duration

Bacteremia without a focus	10 days
Meningitis	2–3 wk
Ventriculitis	4 wk
Osteomyelitis	4 wk

age was <33 wk and 2% in infants whose gestational age was 37 wk or older. The case fatality rate in children aged 3 mo to 14 yr was 9%, and in nonpregnant adults was 11.5%.

Prevention.

Persistent morbidity and mortality from perinatal GBS disease despite advances in neonatal care has spurred intense investigation into modes of prevention. Two basic approaches to GBS prevention have been investigated: (1) elimination of colonization from the mother or infant (chemoprophylaxis), and (2) induction of protective immunity (immunoprophylaxis).

CHEMOPROPHYLAXIS.

Early studies established that administration of antibiotics to pregnant women before the onset of labor does not reliably eradicate maternal GBS colonization and is not an effective means of preventing neonatal GBS disease. However, interruption of neonatal colonization is achievable through administration of antibiotics to the mother during labor. In a prospective, randomized clinical trial in 1986, infants born to GBS-colonized women with premature labor or prolonged rupture of membranes who were given intrapartum chemoprophylaxis had a substantially lower risk of GBS colonization (9% vs 51%) and of early onset disease (0% vs 6%) than did the infants born to women who were not treated. Maternal postpartum febrile illness was also decreased in the treatment group. This strategy of selective intrapartum chemoprophylaxis, while effective, was not initially widely implemented.

In an effort to enhance prevention practice, specific guidelines for maternal chemoprophylaxis were issued by the Centers for Disease Control and Prevention (CDC) in 1996. These guidelines specified administration of intrapartum antibiotics to women identified as high-risk by either culture-based or risk factor–based criteria. These guidelines were revised in 2002 after epidemiologic data indicated the superior protective effect of the culture-based approach in the prevention of neonatal GBS disease. According to current recommendations, vaginorectal GBS screening cultures should be performed for all pregnant women at 35–37 wk gestation. Any woman with a positive prenatal screening culture, GBS bacteriuria during pregnancy, or a previous infant with invasive GBS disease should receive intrapartum antibiotics. Women whose culture status is unknown (culture not done, incomplete, or results unknown) and who deliver prematurely (<37 wk gestation) or experience prolonged rupture of membranes (=18?hr) or intrapartum fever (=38.0°C) should also receive intrapartum chemoprophylaxis. If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent active against GBS should replace GBS prophylaxis. Routine intrapartum prophylaxis is not recommended for women with GBS colonization undergoing planned cesarean delivery who have not begun labor or had rupture of membranes.

These guidelines also suggest an approach for the management of infants born to mothers who received intrapartum chemoprophylaxis (Fig. 169–2). Data from a large epidemiologic study indicate that the administration of maternal intrapartum antibiotics does not change the clinical spectrum or delay the onset of clinical signs in infants who developed GBS disease despite maternal prophylaxis. Thus, the CDC guidelines reserve a full diagnostic evaluation for those infants who appear clinically ill or whose mothers are suspected of having chorioamnionitis.

A significant concern with maternal intrapartum prophylaxis has been that large-scale antibiotic use among parturient women might lead to increased rates of antimicrobial resistance or infection in infants with organisms other than GBS. To date, no GBS strains demonstrating resistance to penicillin have been identified, and increases in the incidence of non-GBS early onset neonatal infections have not been demonstrated in most large epidemiologic studies. Continued surveillance is required in this regard. Penicillin remains the preferred agent for chemoprophylaxis, because of its narrow spectrum and the universal penicillin susceptibility of GBS isolates. Because of recent reports indicating

Figure 169-2 Empirical management of a newborn whose mother received intrapartum antimicrobial agents for prevention of early onset GBS disease or suspected chorioamnionitis. This algorithm is not an exclusive course of management. Variations that incorporate individual circumstances or institutional preferences may be appropriate. If no maternal intrapartum chemoprophylaxis for GBS was administered despite an indication being present, there are insufficient data available upon which to recommend a single management strategy. *Full diagnostic evaluation includes a complete blood count (CBC) and differential, blood culture, and chest radiograph if respiratory abnormalities are present. When signs of sepsis are present, a lumbar puncture, if feasible, should be performed. †Duration of therapy varies depending on the results of the cultures and laboratory testing and the clinical course of the infant. If laboratory results and clinical course do not indicate bacterial infection, duration may be as short as 48?hr. ‡CBC with differential and blood culture. §Applies only to penicillin, ampicillin, or cefazolin and assumes recommended dosing regimens. A healthy-appearing infant who was =38 wk gestational age at delivery and whose mother received =4?hr of intrapartum chemoprophylaxis before delivery may be discharged home after 24?hr if other discharge criteria have been met and a person able to comply fully with instructions for home observation will be present. If any of these conditions is not met, the infant should be observed in the hospital for at least 48?hr and until criteria for discharge are achieved. (Adapted from Centers for Disease Control and Prevention: Prevention of perinatal group B streptococcal disease. Revised guidelines from CDC. *MMWR Morb Mortal Wkly Rep* 2002;51[RR-11]:1–22.)

frequent resistance of GBS to erythromycin (up to 25%) and clindamycin (up to 15%), cefazolin should be used in most cases of intrapartum chemoprophylaxis for penicillin-intolerant women. For penicillin-allergic women at high risk for anaphylaxis, clindamycin or erythromycin should be used, if isolates are demonstrated to be

susceptible. Vancomycin should be used if isolates are resistant to clindamycin and erythromycin or if susceptibility to these agents is unknown.

A limitation of the maternal chemoprophylaxis strategy is that intrapartum antibiotic use is unlikely to have an impact on late-onset neonatal disease, miscarriages or stillbirths attributed to GBS, or adult GBS disease.

MATERNAL IMMUNIZATION.

Another strategy for the prevention of neonatal GBS disease is maternal vaccination. Human studies demonstrate that transplacental transfer of naturally acquired maternal antibody to the GBS capsular polysaccharide protects newborns from invasive GBS infection and that efficient transplacental passage of vaccine-induced GBS antibodies occurs. Conjugate vaccines composed of the GBS capsular polysaccharides coupled to carrier proteins have been produced for human use. In animals, vaccination with these conjugate vaccines induces protective immunity against an otherwise lethal inoculum of GBS in offspring. In early clinical trials, conjugate GBS vaccines were well tolerated and induced levels of functional antibodies well above the range believed to be protective in greater than 90% of recipients. Additional trials are in progress. Administration of a multivalent polysaccharide-protein vaccine before or during pregnancy should lead to transplacental passage of vaccine-induced antibody that protects the fetus and newborn against infection by several GBS serotypes. Such a vaccine would eliminate the need for cumbersome cultures during pregnancy, would circumvent the various risks associated with large-scale antibiotic prophylaxis, and would likely have an impact on both early and late-onset disease. Intrapartum chemoprophylaxis will likely remain an important aspect of prevention, particularly for women in whom opportunities for GBS immunization are missed and for infants born so early that levels of transplacentally acquired antibodies may not be high enough to be protective.

Chapter 170 - Non–Group A or B Streptococci

Michael A. Gerber

The genus *Streptococcus* comprises >30 species. *Streptococcus pneumoniae* (Chapter 167), group A streptococcus (Chapter 168), and group B streptococcus (Chapter 169) are the most common causes of human streptococcal infections. The ß-hemolytic streptococci of Lancefield groups C to H and K to O and the nontypable strains that cause a-hemolysis (the **viridans streptococci**) also cause infections in humans (Table 170–1). These organisms commonly colonize intact body surfaces (e.g., the pharynx, skin, gastrointestinal, and genitourinary tracts). Of the non–group A ß-hemolytic streptococci, groups C and G streptococcus are the most frequent cause of human disease. Until recently, the enterococci were classified among the group D streptococci but are now a separate genus, *Enterococcus* (Chapter 171).

Group C streptococcus is a much more common cause of infection in animals than in humans. Humans infected with this organism often have had some animal contact. Both group C and group G streptococcus often can be part of the normal human flora of the nasopharynx, skin, and genital tract. Group C streptococcus also can be cultured from the umbilicus of asymptomatic newborns and from routine puerperal vaginal cultures. Group G streptococcus also can be cultured from the gastrointestinal tract. Because of the relatively low virulence of group C and group G streptococci, most humans infected with either of these organisms have some underlying medical disorder (e.g., diabetes mellitus, malignancy, alcohol abuse, immunosuppression).

The clinical features of both group C and group G streptococcal pharyngitis are similar to those of group A streptococcal pharyngitis with fever, mild to moderate sore throat, pharyngeal exudate, and cervical lymphadenitis. Several studies have demonstrated that group C streptococcus is a relatively common cause of acute pharyngitis among college students and among adults who come to an emergency department. In addition to endemic pharyngitis, group C streptococcus can cause epidemic food-borne pharyngitis after ingestion of contaminated products, such as unpasteurized cow's milk. Family and school outbreaks of group C streptococcal pharyngitis have also been described. Group C streptococcus also has been reported as an uncommon cause of a number of other infections, including skin and soft tissue infections, septic arthritis, osteomyelitis, pneumonitis, infective endocarditis, bacteremia and septicemia, meningitis, epiglottitis, pericarditis, urinary tract infections, and sinusitis. These organisms also have been associated with epidemic and nonepidemic cases of puerperal sepsis and endometritis. Recent reports have suggested an association between group C streptococcus and reactive arthritis, as well as a toxic shock–like syndrome.

Even though there have been several well-documented food-borne outbreaks of group G streptococcal pharyngitis, the etiologic role of group G streptococcus in acute, endemic pharyngitis remains unclear. Recently, a community-wide, respiratory outbreak of group G streptococcal pharyngitis in a pediatric population was described in which group G streptococcus was isolated from 56 of 222 (25%) consecutive children with acute pharyngitis seen at a private pediatric office. Results of DNA fingerprinting of the group G streptococcal isolates suggested that 75% of them were the same strain. The patients with group G streptococcal pharyngitis were comparable to those with group A streptococcal pharyngitis with respect to clinical findings, antistreptolysin O titer response, and clinical response to antibiotic therapy. These

findings suggested that antibiotic therapy may have impact on the clinical course of group G streptococcal pharyngitis.

Group G streptococcus has been reported to be an uncommon cause of puerperal sepsis and a neonatal infection that is clinically similar to early onset group B streptococcal disease. Other infections occasionally caused by group G streptococcal include bacteremia, endocarditis, septic arthritis, osteomyelitis, pneumonia, erysipelas and other skin and soft tissue infections, and meningitis. Recently, group G streptococcus has been associated with a toxic shock–like syndrome.

Acute rheumatic fever has not been described as a complication of either group C or group G streptococcal pharyngitis, and, although there have been reports attempting to link acute glomerulonephritis with group G streptococcal pharyngitis, the evidence is anecdotal and a causal relationship has not been established. Acute glomerulonephritis has been reported as a complication of group C streptococcal pharyngitis; however, it is extremely unusual. Therefore, the primary reason to identify either group C or group G streptococcus as the etiologic agent of acute pharyngitis is to initiate antibiotic therapy that may reduce the clinical impact of the illness. However, there is currently no convincing evidence from controlled studies of a clinical response to antibiotic therapy in patients with acute pharyngitis and either group C or group G streptococcus isolated from their upper respiratory tract.

Penicillin is the antibiotic of choice for treating infections due to either group C or group G streptococcus. Pharyngitis usually is treated in a similar manner to group A streptococcal upper respiratory infections, whereas more severe infections require parenteral therapy.

Chapter 171 - *Enterococcus*

David B. Haslam

Enterococcus, long recognized as a pathogen in select populations, in the past 2 decades has become a common and particularly troublesome cause of hospital-acquired infection. These organisms, formerly classified with *Streptococcus bovis* and *Streptococcus equinus* as the Lancefield group D streptococcus, are now placed in a separate genus and are notorious for their frequent resistance to antibiotics.

Etiology.

Enterococci are gram-positive, catalase-negative facultative anaerobes that grow in pairs or short chains. Most are nonhemolytic (also called ?-hemolytic) on sheep's blood agar, although some isolates have a- or ß-hemolytic activity. Enterococci are distinguished from most Lancefield groupable streptococci by their ability to grow in bile and hydrolyze esculin. Enterococci are able to grow in 6.5% NaCl and hydrolyze L-pyrrolidonyl-ß-naphthylamide (the PYR reaction), features used by clinical laboratories to distinguish *Enterococcus* from group D streptococcus. Identification at the species level is enabled by differing patterns of carbohydrate fermentation.

Epidemiology.

Enterococci are normal inhabitants of the gastrointestinal tract of humans and animals. Oral secretions and dental plaque, the upper respiratory tract, skin, and vagina may also be colonized by *Enterococcus. E. faecalis* is the predominant organism, with colonization commonly occurring in the 1st week of life. By the time of adulthood, *E. faecalis* colonization is nearly ubiquitous. *E. faecium* colonization is less consistent, although approximately 25% of adults harbor this organism.

E. faecalis accounts for 80–90% of enterococcal infections, with almost all of the remaining infections caused by *E. faecium*. Only rarely are other species, such as *E. gallinarium* and *E. cassiliflavus*, associated with invasive infection but these organisms are notable for their intrinsic low-level vancomycin resistance. Typically, the patient's indigenous flora is presumed to be the source of enterococcal infection. However, direct spread from person to person or from contaminated medical devices

occur, particularly within newborn nurseries and intensive care units. Recent studies have demonstrated the importance of nosocomial spread as a source of hospital outbreaks.

Pathogenesis.

Enterococci are not aggressively invasive organisms, usually only causing disease in children with damaged mucosal surfaces or impaired immune response. Their dramatic emergence as a cause of nosocomial infection is predominantly due to their resistance to antibiotics commonly used in the hospital setting. Aside from antibiotic resistance genes, few classic virulence factors have been described among enterococci. Adhesion promoting factors likely account for the propensity of these organisms to cause endocarditis and urinary tract infections (UTIs). Many isolates also produce a **cytolysin** that has a broad range of host cells. Released at high bacterial density in a process called quorum sensing, cytolysin contributes to virulence in experimental models of endocarditis, peritonitis, and endophthalmitis. Other proposed virulence factors include aggregation substance, gelatinase, extracellular superoxide, and extracellular surface protein.

ANTIMICROBIAL RESISTANCE.

Enterococci are highly resistant to cephalosporins and semisynthetic penicillins such as nafcillin, oxacillin, and methicillin. They are moderately resistant to extended spectrum penicillins such as ticarcillin and carbenicillin. Ampicillin, imipenem, and penicillin are the most active ß-lactams against these organisms. Any active drug may be insufficient if used alone for serious infections wherein high bactericidal activity is desired. Some strains of *E. faecalis* produce a plasmid-encoded ß-lactamase similar to that found in *Staphylococcus*. These isolates are completely resistant to penicillins, necessitating the combination of a penicillin plus a ß-lactamase inhibitor or the use of imipenem or vancomycin.

All enterococci have intrinsic low-level resistance to aminoglycosides because these antibiotics are poorly transported across the *Enterococcus* cell wall (Box 171–1). Concomitant use of a cell wall active agent, such as a ß-lactam or glycopeptide antibiotic, improves permeability of the cell wall for the aminoglycosides, resulting in synergistic killing. However, some isolates demonstrate high-level resistance, defined as mean inhibitory concentration (MIC >2,000?µg/mL) due to modification or inactivation of aminoglycoside agents. Strains demonstrating high-level resistance, and even some moderately resistant isolates, are not affected synergistically by aminoglycosides and cell wall–active antibiotics.

Resistance to almost all other antibiotic classes, including tetracyclines, macrolides, and chloramphenicol, has been described among the enterococci, necessitating individual susceptibility testing for these antibiotics when their use is considered. Despite apparent susceptibility in vitro, trimethoprim-sulfamethoxazole has poor

activity in vivo, and should not be used as the primary agent against *Enterococcus* infections.

Box 171-1. Antimicrobial Resistance of *Enterococcus*

INTRINSIC RESISTANCE (CHROMOSOMALLY ENCODED)

- Aminoglycosides (low level)
- ß-lactams (especially semisynthetic penicillins and cephalosporins)
- Trimethoprim-sulfamethoxazole
- Clindamycin (low level)

ACQUIRED RESISTANCE

- Aminoglycosides (high level)
- Chloramphenicol
- Erythromycin and high-level clindamycin
- Quinolones
- Penicillins (ß-lactamase)
- Tetracyclines
- Vancomycin
- Streptogammins
- Oxazolidinones

Vancomycin has traditionally been effective against multiresistant isolates, but resistance to vancomycin and other glycopeptides, including teicoplanin and daptomycin, is increasingly common. Both high- and moderate-level resistance are described in *E. faecalis* and *E. faecium*. High-level resistance (MIC = 64?µg/ mL) can be transferred by way of conjugation and is usually due to plasmid-mediated transfer of the *vanA* gene. High-level resistance is most common among *E. fecium* but is increasingly seen among *E. faecalis* isolates. Moderate-level resistance (MIC 8–256?µg/mL) results from a chromosomal homologue of *vanA*, known as *vanB*. Isolates that harbor the *vanB* gene are only moderately resistant to vancomycin and initially demonstrate susceptibility to teicoplanin, although resistance can emerge during therapy.

Clinical Manifestations.

Among pediatric patients, *Enterococcus* infections traditionally occurred predominantly in newborn infants. However, infection in older children is increasingly common. Most *Enterococcus* infections occur in patients with breakdown of normal physical barriers such as the gastrointestinal tract, skin, or urinary tract. Other risk factors for *Enterococcus* infection include prolonged hospitalization, indwelling vascular catheters, prior use of antibiotics, and compromised immunity.

NEONATAL INFECTIONS.

Enterococcus accounts for up to 15% of all neonatal bacteremia and septicemia. Like group B streptococcus infections, *Enterococcus* infections are seen in two distinct settings in neonatal patients. Early onset infection (<7 days of age) may mimic early onset group B streptococcus septicemia, but tends to be milder. Early onset *Enterococcus* sepsis most often occurs in full-term infants who are otherwise healthy. Late-onset infection (=7 days of age) is associated with risk factors such as extreme prematurity, presence of an intravascular catheter, or necrotizing enterocolitis, or it follows an intra-abdominal surgical procedure. Symptoms in late-onset disease are more severe than those in early onset disease and include apnea, bradycardia, and deteriorating respiratory function. Focal infections such as scalp abscess and catheter infection are commonly associated. Mortality rates range from 6% in early onset septicemia to 15% in late-onset infections associated with necrotizing enterocolitis.

Enterococci are an occasional cause of meningitis. In neonates in particular, meningitis usually occurs as a complication of septicemia. Alternatively, the organism may gain access to the central nervous system by way of contiguous spread, such as through neural tube defect or in association with an intraventricular shunt. *Enterococcus* meningitis can be associated with minimal abnormality of cerebrospinal fluid.

INFECTIONS IN OLDER CHILDREN.

Enterococcus rarely causes UTI in healthy children, but accounts for approximately 15% of cases of nosocomially acquired UTI, both in children and adults. Presence of an indwelling urinary catheter is the major risk factor for nosocomial UTI. Enterococci are frequently isolated in intra-abdominal infections following intestinal perforation or surgery. Their significance in polymicrobial infections has been questioned, although reported mortality rates are higher when intra-abdominal infections include *Enterococcus. Enterococcus* is less commonly associated with bacteremia and endocarditis in children than in adults. Predisposing factors include an indwelling central venous catheter, gastrointestinal surgery, immunodeficiency, and

cardiovascular abnormalities.

Treatment.

Treatment of invasive *Enterococcus* infections must recognize that these organisms are frequently resistant to antimicrobial agents. In general, in the immunocompetent host, minor localized infections due to *Enterococcus* can be treated with ampicillin alone. Antibiotics containing ß-lactamase inhibitors (clavulanate or sulbactam) provide advantage only for the few organisms whose resistance is due to production of ß-lactamase. In uncomplicated UTIs, nitrofurantoin is efficacious when the organism is known to be sensitive to this antibiotic.

Invasive infections such as sepsis, meningitis, and endocarditis are usually treated with a combination of penicillin or ampicillin and an aminoglycoside when the isolate is susceptible. Vancomycin can be substituted for the penicillins in allergic patients, but should be used with an aminoglycoside, because vancomycin alone is not bacteriocidal. Endocarditis from strains possessing high-level aminoglycoside resistance may relapse even after prolonged therapy. High-dose or continuous infusion penicillin has been proposed for treatment of these infections in adults, yet ultimately valve replacement may be necessary. In patients with catheter-associated enterococcal bacteremia, the catheter should be removed promptly in almost all cases.

VANCOMYCIN-RESISTANT *ENTEROCOCCUS*.

The treatment of serious infections due to multiresistant, vancomycin-resistant strains is particularly challenging. Quinupristin–dalfopristin is a combined streptogammin antibiotic that inhibits bacterial protein synthesis at two different stages. It has activity against most *E. faecium* strains, including those with high-level vancomycin resistance. Approximately 90% of *E. faecium* strains are susceptible to quinupristin–dalfopristin in vitro. Notably, it is inactive against *E. faecalis* and therefore should not be used as the sole agent against gram-positive organisms until culture results exclude the presence of *E. faecalis*. Studies in children suggest that this antibiotic is effective and generally well tolerated. Emergence of resistance to quinupristin–dalfopristin is rare, but has been demonstrated.

Linezolid, an oxazolidinone antibiotic that inhibits protein synthesis, is bacteriostatic against most *E. faecium* and *E. faecalis*, including vancomycin-resistant isolates. Response rates are generally >90%, including cases of bacteremia and sepsis. Anecdotal reports reveal the success of linezolid in treating meningitis due to vancomycin-resistant enterococci. As seen with other antibiotics, however, linezolid resistance is documented and nosocomial spread of these organisms can occur.

Prevention.

Strategies for preventing enterococcal infections include early removal of urinary and intravenous catheters and debridement of necrotic tissue. Infection control strategies, including surveillance cultures, patient and staff cohorting, and strict gown and glove isolation are effective at decreasing colonization rates with vancomycin-resistant enterococci. However, these organisms may persist on inanimate objects, such as stethoscopes, complicating efforts to limit their nosocomial spread. To prevent the emergence and spread of vancomycin-resistant organisms, the Centers for Disease Control and Prevention has developed a series of guidelines for prudent vancomycin use.

Chapter 172 - Diphtheria (*Corynebacterium diphtheriae*)

Sarah S. Long

Diphtheria is an acute toxic infection caused by *Corynebacterium diphtheriae*. Diphtheria was the first infectious disease to be conquered on the basis of principles of microbiology, immunology, and public health. Although diphtheria was reduced from a major cause of childhood death in the Western hemisphere in the early 20th century to a medical rarity, modern reminders of the fragility of such success underscore the need to apply those same principles assiduously in an era of vaccine dependence and a single global community.

Etiology.

Corynebacterium is an aerobic, nonencapsulated, non– spore-forming, mostly nonmotile, pleomorphic, gram-positive bacillus. Not fastidious in growth requirements, its isolation is enhanced by use of a selective medium (i.e., cystine-tellurite blood agar) that inhibits growth of competing organisms and, when reduced by *C. diphtheriae*, renders colonies gray-black. Three biotypes (i.e., *mitis, gravis*, and *intermedius*), each capable of causing diphtheria, are differentiated by colonial morphology, hemolysis, and fermentation reactions. A lysogenic bacteriophage carrying the gene that encodes for production of exotoxin confers diphtheria-producing potential to strains of *C. diphtheriae*, but it provides no essential protein to the bacterium. Indigenous nontoxigenic *C. diphtheriae* can be rendered toxigenic and disease-producing after importation of toxigenic *C. diphtheriae*. Diphtheritic toxin can be demonstrated in vitro by the agar immunoprecipitin technique (Elek test), by polymerase chain reaction, or by the in vivo toxin neutralization test in guinea pigs. Toxigenic and nontoxigenic strains are indistinguishable by colony type, microscopy, or biochemical tests.

Epidemiology.

Unlike other **diphtheroids** (**coryneform bacteria**), which are ubiquitous in nature, *C. diphtheriae* is an exclusive inhabitant of human mucous membranes and skin. Spread is primarily by airborne respiratory droplets, direct contact with respiratory secretions of symptomatic individuals, or exudate from infected skin lesions. Asymptomatic respiratory tract carriers are important in transmission. Where

diphtheria is endemic, 3–5% of healthy individuals may harbor toxigenic organisms, but carriage is exceedingly rare if diphtheria is rare. Skin infection and skin carriage are silent reservoirs of diphtheria. Viability in dust and on fomites for up to 6 mo has less epidemiologic significance. Transmission through contaminated milk and an infected food handler has been proved or suspected.

In the 1920s, more than 125,000 cases and 10,000 deaths due to diphtheria were reported annually in the United States, with highest fatality rates among very young and elderly patients. From 1921–1924, diphtheria was the leading cause of death among Canadian children 2–14 yr of age. The incidence then began to decrease, and with the widespread use of diphtheria toxoid in the United States after World War II, it declined steadily, with dramatic reductions in the latter 1970s. Since then, there have been five or fewer cases per year and no epidemics of respiratory tract diphtheria. Similar decreases occurred in Europe.

Although disease incidence has decreased worldwide, diphtheria remains endemic in many developing countries.

When diphtheria was endemic, it primarily affected children <15 yr of age, but epidemiology has shifted to adults who lack natural exposure to toxigenic *C. diphtheriae* in the vaccine era and have low rates of booster vaccinations. In the 27 sporadic cases of respiratory tract diphtheria reported in the United States in the 1980s, 70% occurred in persons >25 yr of age. The largest outbreak of diphtheria in the developed world since the 1960s occurred from 1990–1996 throughout the newly independent countries of the former Soviet Union, causing >150,000 cases in 14 of 15 countries. More than 60% of cases occurred in individuals >14 yr of age. Case fatality rates ranged from 3–23% by state. Factors contributing to the epidemic included a large population of underimmunized adults, decreased childhood immunization, population migration, crowding, and failure to respond aggressively during early phases of the epidemic. Cases of diphtheria among travelers from these endemic areas were transported to many countries in Europe.

Most proven cases of respiratory tract diphtheria in the United States in the 1990s have been associated with importation of toxigenic *C. diphtheriae*, although clonally related, toxigenic *C. diphtheriae* has been demonstrated to persist in the United States and Canada for at least 25 years despite rarity of cases. Protection from serious disease from importation or indigenous exposure depends on immunization.

The estimated minimum protective level of diphtheria antitoxin is 0.01–0.1?IU/mL; the precise protective limit has not been defined. In outbreaks, 90% of individuals with clinical disease have had antibody values <0.01?IU/mL, and 92% of asymptomatic carriers have had values >0.1?IU/mL. In serosurveys in the United States and Western Europe where almost universal immunization during childhood has been achieved, 25% to more than 60% of adults lack protective antitoxin levels, with very low levels especially in the elderly.

Cutaneous diphtheria, a curiosity when diphtheria was common, accounted for >50% of *C. diphtheriae* isolates reported in the United States by 1975. This indolent local infection, compared with mucosal infection, is associated with more prolonged bacterial shedding, increased contamination of the environment, and increased transmission to the pharynx and skin of close contacts. Outbreaks are associated with homelessness, crowding, poverty, alcoholism, poor hygiene, contaminated fomites, underlying dermatosis, and introduction of new strains from exogenous sources. No longer a tropical or subtropical disease, 1,100 *C. diphtheriae* infections were documented in a neighborhood in Seattle, WA, from 1971–1982; 86% were cutaneous, and 40% involved toxigenic strains. Cutaneous diphtheria is an important reservoir for toxigenic *C. diphtheriae* in the United States and is a frequent mode of importation of source cases for subsequent sporadic respiratory tract diphtheria. In an attempt to focus attention on respiratory tract diphtheria, which is much more likely to cause acute obstructive complications and toxic manifestations, skin isolates of *C. diphtheriae* were removed from annual diphtheria statistics reported by the Centers for Disease Control and Prevention (CDC) after 1979.

Pathogenesis.

Toxigenic and nontoxigenic *C. diphtheriae* organisms cause skin and mucosal infection and rarely can cause focal infection after bacteremia. The organism usually remains in the superficial layers of skin lesions or respiratory tract mucosa, inducing local inflammatory reaction. The major virulence of the organism lies in its ability to produce the potent 62-kd polypeptide exotoxin, which inhibits protein synthesis and causes local tissue necrosis. Within the first few days of respiratory tract infection, a dense necrotic coagulum of organisms, epithelial cells, fibrin, leukocytes, and erythrocytes forms, advances, and becomes a gray-brown adherent **pseudomembrane.** Removal is difficult and reveals a bleeding edematous submucosa. Paralysis of the palate and hypopharynx is an early local effect of the toxin. Toxin absorption can lead to necrosis of kidney tubules, thrombocytopenia, cardiomyopathy, and demyelination of nerves. Because the latter two complications can occur 2–10 wk after mucocutaneous infection, the pathophysiologic mechanism in some cases is suspected to be immunologically mediated.

Clinical Manifestations.

The manifestations of *C. diphtheriae* infection are influenced by the anatomic site of infection, the immune status of the host, and the production and systemic distribution of toxin.

RESPIRATORY TRACT DIPHTHERIA.

In the classic description of 1,400 cases of diphtheria in California in 1954, the primary focus of infection was the tonsils or pharynx in 94%, with the nose and larynx being the next two most common sites. After an average incubation period of 2–4 days, local signs and symptoms of inflammation develop. Infection of the anterior nares, which is more common among infants, causes serosanguineous, purulent, erosive rhinitis with membrane formation. Shallow ulceration of the external nares and upper lip is characteristic. In tonsillar and pharyngeal diphtheria, sore throat is a universal early symptom, but only half of patients have fever, and fewer have dysphagia, hoarseness, malaise, or headache. Mild pharyngeal injection is followed by unilateral or bilateral tonsillar membrane formation, which extends variably to affect the uvula, soft palate, posterior oropharynx, hypopharynx, and glottic areas.

Underlying soft tissue edema and enlarged lymph nodes can cause a **bull-neck appearance**. The degree of local extension correlates directly with profound prostration, bull-neck appearance, and fatality due to airway compromise or toxin-mediated complications.

The leather-like adherent membrane, extension beyond the faucial area, relative lack of fever, and dysphagia help differentiate diphtheria from exudative pharyngitis due to group A streptococcus and Epstein-Barr virus. Vincent angina, infective phlebitis and thrombosis of the jugular veins, and mucositis in patients undergoing cancer chemotherapy are usually differentiated by the clinical setting. Infection of the larynx, trachea, and bronchi can be primary or a secondary extension from the pharyngeal infection. Hoarseness, stridor, dyspnea, and croupy cough are clues. Differentiation from bacterial epiglottitis, severe viral laryngotracheobronchitis, and staphylococcal or streptococcal tracheitis hinges partially on the relative paucity of other signs and symptoms in patients with diphtheria and primarily on visualization of the adherent pseudomembrane at the time of laryngoscopy and intubation.

Patients with laryngeal diphtheria are highly prone to suffocation because of edema of soft tissues and the obstructing dense cast of respiratory epithelium and necrotic coagulum. Establishment of an artificial airway and resection of the pseudomembrane are lifesaving, but further obstructive complications are common, and systemic toxic complications are inevitable.

CUTANEOUS DIPHTHERIA.

Classic cutaneous diphtheria is an indolent, nonprogressive infection characterized by a superficial, ecthymic, nonhealing ulcer with a gray-brown membrane. Diphtheritic skin infections cannot always be differentiated from streptococcal or staphylococcal impetigo, and they frequently coexist. In most cases, underlying dermatoses, lacerations, burns, bites, or impetigo have become secondarily contaminated. Extremities are more often affected than the trunk or head. Pain, tenderness, erythema, and exudate are typical. Local hyperesthesia or hypesthesia is unusual. Respiratory tract colonization or symptomatic infection and toxic complications occur in the minority of patients with cutaneous diphtheria. Among infected Seattle adults, 3% with cutaneous infections and 21% with symptomatic nasopharyngeal infection, with or without skin involvement, had toxic myocarditis, neuropathy, or

obstructive respiratory tract complications. All had received at least 20,000?U of equine antitoxin at the time of hospitalization.

INFECTION AT OTHER SITES.

C. diphtheriae occasionally causes mucocutaneous infections at other sites, such as the ear (otitis externa), eye (purulent and ulcerative conjunctivitis), and genital tract (purulent and ulcerative vulvovaginitis). The clinical setting, ulceration, membrane formation, and submucosal bleeding help differentiate diphtheria from other bacterial and viral causes. Rare cases of septicemia are described and are universally fatal. Sporadic cases of endocarditis occur, and clusters among intravenous drug users have been reported in several countries; skin was the probable portal of entry, and almost all strains were nontoxigenic. Sporadic cases of pyogenic arthritis, mainly due to nontoxigenic strains, have been reported in adults and children. Diphtheroids isolated from sterile body sites should not be dismissed as contaminants without careful consideration of the clinical setting.

TOXIC CARDIOMYOPATHY.

Toxic cardiomyopathy occurs in approximately 10–25% of patients with diphtheria and is responsible for 50–60% of deaths. Subtle signs of myocarditis can be detected in most patients, especially the elderly, but the risk for significant complications correlates directly with the extent and severity of exudative local oropharyngeal disease and delay in administration of antitoxin. The first evidence of cardiac toxicity characteristically occurs in the 2nd–3rd wk of illness as pharyngeal disease improves but can appear acutely as early as the 1st wk, when a fatal outcome is likely, or insidiously as late as the 6th wk of illness. Tachycardia out of proportion to fever is common and may be evidence of cardiac toxicity or autonomic nervous system dysfunction. A prolonged PR interval and changes in the ST-T wave on an electrocardiographic tracing are relatively frequent findings, and dilated and hypertrophic cardiomyopathy detected by echocardiogram have been described. Single or progressive cardiac dysrhythmias can occur, such as first-, second-, and third-degree heart block; atrioventricular dissociation; and ventricular tachycardia. Clinical congestive heart failure may have an insidious or acute onset. Elevation of the serum aspartate aminotransferase concentration closely parallels the severity of myonecrosis. Severe dysrhythmia portends death. Histologic postmortem findings may show little or diffuse myonecrosis with acute inflammatory response. Recovery from toxic myocardiopathy is usually complete, although survivors of more severe dysrhythmias can have permanent conduction defects.

TOXIC NEUROPATHY.

Neurologic complications parallel the extent of primary infection and are multiphasic in onset. Acutely or 2–3 wk after onset of oropharyngeal inflammation, hypesthesia and local paralysis of the soft palate occur commonly. Weakness of the posterior pharyngeal, laryngeal, and facial nerves may follow, causing a nasal quality in the voice, difficulty in swallowing, and risk of death due to aspiration. Cranial neuropathies characteristically occur in the 5th wk and lead to oculomotor and ciliary paralysis, which are manifested as strabismus, blurred vision, or difficulty with accommodation. Symmetric polyneuropathy has its onset 10 days–3 mo after oropharyngeal infection and causes principally motor deficits with diminished deep tendon reflexes. Proximal muscle weakness of the extremities progressing distally and, more commonly, distal weakness progressing proximally have been described. Clinical and cerebrospinal fluid findings in the latter are indistinguishable from those of Guillain-Barré syndrome. Paralysis of the diaphragm can ensue. Complete recovery is likely. Rarely, 2–3 wk after onset of illness, dysfunction of the vasomotor centers can cause hypotension or cardiac failure.

Diagnosis.

Specimens for culture should be obtained from the nose and throat and any other mucocutaneous lesion. A portion of membrane should be removed and submitted with underlying exudate. The laboratory must be notified to use selective medium. *C. diphtheriae* survives drying. In remote areas, a swab specimen can be placed in a silica gel pack and sent to a reference laboratory. Evaluation of a direct smear using Gram stain or specific fluorescent antibody is unreliable. Culture isolates of coryneform organisms should be identified to the species level, and toxigenicity and antimicrobial susceptibility tests should be performed for *C. diphtheriae* isolates.

Treatment.

Specific antitoxin is the mainstay of therapy and should be administered on the basis of clinical diagnosis, because it neutralizes only free toxin. Efficacy diminishes with elapsing time after the onset of mucocutaneous symptoms. Equine diphtheria antitoxin is available in the United States only from the CDC. Physicians treating a case of suspected diphtheria can contact the CDC diphtheria duty officer (404-639-8255, 8 am–4:30 pm ET; 404-639-2889, all other times). Antitoxin is administered as a single empirical dose of 20,000–120,000?U based on the degree of toxicity, site and size of the membrane, and duration of illness. Antitoxin is probably of no value for local manifestations of cutaneous diphtheria, but its use is prudent because toxic sequelae can occur. Commercially available intravenous immunoglobulin preparations contain low titers of antibodies to diphtheria toxin; their use for therapy of diphtheria is not proved or approved. Antitoxin is not recommended for asymptomatic carriers.

Antimicrobial therapy is indicated to halt toxin production, treat localized infection, and prevent transmission of the organism to contacts. *C. diphtheriae* is usually susceptible to various agents in vitro, including penicillins, erythromycin, clindamycin, rifampin, and tetracycline. Resistance to erythromycin is common in populations if the drug has been used broadly. Only penicillin or erythromycin is recommended; erythromycin is marginally superior to penicillin for eradication of nasopharyngeal carriage. Appropriate therapy is erythromycin (40–50?mg/kg/24?hr divided q 6?hr PO or IV; maximum: 2?g/24?hr), aqueous crystalline penicillin G (100,000–150,000?U/kg/24?hr divided q 5?h IV or IM), or procaine penicillin (25,000–50,000?U/kg/24?hr divided q 12?h IM). Antibiotic therapy is not a substitute for antitoxin therapy. Therapy is given for 14 days. Some patients with cutaneous diphtheria have been treated for 7–10 days. Elimination of the organism should be documented by at least two successive cultures from the nose and throat (or skin) obtained 24?hr apart after completion of therapy. Treatment with erythromycin is repeated if the culture result is positive.

Patients with pharyngeal diphtheria are placed in respiratory isolation, and patients with cutaneous diphtheria are placed in contact isolation until the cultures taken after cessation of therapy are negative. Cutaneous wounds are cleaned thoroughly with soap and water. Bed rest is essential during the acute phase of disease, usually for 2 wk or more until the risk of symptomatic cardiac damage has passed, with a return to physical activity guided by the degree of toxicity and cardiac involvement.

Complications.

Respiratory tract obstruction by pseudomembranes may require bronchoscopy or intubation and mechanical ventilation. Recovery from the myocarditis and neuritis is often slow but usually complete. Corticosteroids do not diminish these complications and are not recommended.

Prognosis.

The prognosis for patients with diphtheria depends on the virulence of the organism (subspecies *gravis* has the highest fatality), age, immunization status, site of infection, and speed of administration of the antitoxin. Mechanical obstruction from laryngeal diphtheria or bull-neck diphtheria and the complications of myocarditis account for most diphtheria-related deaths.

The case fatality rate of almost 10% for respiratory tract diphtheria has not changed in 50 yr; the rate was 18% in a Swedish outbreak in the 1990s. At recovery, administration of diphtheria toxoid is indicated to complete the primary series or booster doses of immunization, because not all patients develop antibodies after infection.

Prevention.

All suspected diphtheria cases should be reported to local and state health departments. Investigation is aimed at preventing secondary cases in exposed individuals and at determining the source and carriers to halt spread to unexposed individuals. Reported rates of carriage in household contacts of case patients are 0–25%. The risk of developing diphtheria after household exposure to a case is approximately 2%, and the risk is 0.3% after similar exposure to a carrier.

ASYMPTOMATIC CASE CONTACTS.

All household contacts and those who have had intimate respiratory or habitual physical contact with a patient are closely monitored for illness through the 7-day incubation period. Cultures of the nose, throat, and any cutaneous lesions are performed. Antimicrobial prophylaxis is given, regardless of immunization status, using erythromycin (40–50?mg/kg/24?hr divided qid PO for 7 days; maximum: 2?g/24?hr) or a single injection of benzathine penicillin G (600,000?U IM for <30?kg, 1,200,000?U IM for =30?kg). The efficacy of antimicrobial prophylaxis is presumed but not proved. Diphtheria toxoid vaccine, in age-appropriate form, is given to immunized individuals who have not received a booster dose within 5 yr. Children who have not received their fourth dose should be vaccinated. Those who have received fewer than three doses of diphtheria toxoid or who have uncertain immunization status are immunized with age-appropriate preparation on a primary schedule.

ASYMPTOMATIC CARRIERS.

When an asymptomatic carrier is identified, antimicrobial prophylaxis is given for 7 days and an age-appropriate preparation of diphtheria toxoid is administered immediately if a booster has not been given within 1 yr. Individuals are placed in respiratory isolation (respiratory tract colonization) or contact isolation (cutaneous colonization only) until at least two subsequent cultures obtained 24?hr apart after cessation of therapy are negative.

Repeat cultures are performed =2 wk after completion of therapy for cases and carriers, and, if positive, an additional 10-day course of oral erythromycin should be given and follow-up cultures performed. Susceptibility testing of isolates should be performed as erythromycin resistance is reported. Neither antimicrobial agent eradicates carriage in 100% of individuals. In one report, 21% of carriers had failure of eradication after a single course of therapy. Antitoxin is not recommended for asymptomatic close contacts or carriers, even if inadequately immunized. Transmission of diphtheria in modern hospitals is rare. Only those with an unusual contact with respiratory or oral secretions should be managed as contacts. Investigation of the casual contacts of patients and carriers or persons in the community without known exposure has yielded extremely low carriage rates and is not routinely recommended.

VACCINE.

Universal immunization with diphtheria toxoid throughout life to provide constant protective antitoxin levels and to reduce indigenous *C. diphtheriae* is the only effective control measure. Although immunization does not preclude subsequent respiratory or cutaneous carriage of toxigenic *C. diphtheriae*, it decreases local tissue spread, prevents toxic complications, diminishes transmission of the organism, and provides herd immunity when at least 70–80% of a population is immunized.

Diphtheria toxoid is prepared by formaldehyde treatment of toxin, standardized for potency, and adsorbed to aluminum salts, which enhance immunogenicity. Two preparations of diphtheria toxoids are formulated according to the limit of flocculation (Lf) content, a measure of the quantity of toxoid. The pediatric preparation (i.e., DTaP, DT, DTP) contains 6.7–25.0?Lf units of diphtheria toxoid per 0.5-mL dose; the adult preparation (i.e., dT) contains no more than 2?Lf units of toxoid per 0.5-mL dose. The higher-potency (i.e., D) formulation of toxoid is used for primary series and booster doses for children through 6 yr of age because of superior immunogenicity and minimal reactogenicity. For individuals 7 yr of age or older, dT is recommended for the primary series and booster doses because the lower concentration of diphtheria toxoid is adequately immunogenic and because increasing the content of diphtheria toxoid heightens reactogenicity with increasing age.

For children from 6 wk to their 7th birthday, five 0.5-mL doses of diphtheria-containing (D) vaccine are given in a primary series, including three doses at 2, 4, and 6 mo of age, with a fourth dose, an integral part of the primary series, 6–12 mo after the third dose. A booster dose is given at 4–6 yr of age (unless the fourth primary dose was administered after the 4th birthday). For persons 7 yr of age and older, three 0.5-mL doses of diphtheria-containing (d) vaccine are given in a primary series of two doses 4–8 wk apart and a third dose 6–12 mo after the second dose. The only contraindication to tetanus and diphtheria toxoid is a history of neurologic or severe hypersensitivity reaction after a previous dose. For children <7 yr of age in whom pertussis immunization is contraindicated, DT is used. Those begun with DTaP, DTP, or DT before 1 yr of age should have a total of five 0.5-mL doses of diphtheria-containing (D) vaccines by 6 yr of age. For those beginning =1 yr of age, the primary series is three 0.5-mL doses of diphtheria-containing (D) vaccine, with a booster given at 4–6 yr, unless the third dose was given after the 4th birthday.

Booster doses of 0.5?mL of dT should be given every 10 yr starting at 11–12 yr of age and no later than by 16 yr of age. Vaccination with diphtheria toxoid should be used whenever tetanus toxoid is indicated, to ensure continuing diphtheria immunity.

There is no known association of DT or dT with increased risk of convulsions. Local side effects alone do not preclude continued use. Persons who experience Arthus-type hypersensitivity reactions or a temperature =103°F (39.4°C) after a dose of dT (rare in childhood) usually have high serum tetanus antitoxin levels and should not be given dT more frequently than every 10 yr, even if a significant tetanus-prone injury is sustained. DT or dT preparation can be given concurrently with other vaccines. *Haemophilus influenzae* conjugate vaccines containing diphtheria toxoid (PRP-D) or the variant of diphtheria toxin, CRM_{197} protein (HbOC), are not substitutes for diphtheria toxoid immunization and do not appear to affect reactogenicity.

Chapter 173 - *Listeria monocytogenes*

Robert S. Baltimore

Listeriosis in humans is caused principally by *Listeria monocytogenes*, one of seven species of the genus *Listeria* that are widely distributed in the environment and throughout the food chain. Human infections can usually be traced to an animal reservoir. Infection occurs most commonly at the extremes of age. In the pediatric population, perinatal infections predominate and usually occur secondary to maternal infection or colonization. Outside the newborn period, disease is most commonly encountered in immunosuppressed children and adults and in the elderly. In the United States, food-borne outbreaks are caused by improperly processed dairy products and contaminated vegetables, and they principally affect the same individuals at risk for sporadic disease.

Etiology.

Members of the genus *Listeria* are facultatively anaerobic, non–spore-forming, motile, gram-positive bacilli. The seven *Listeria* species are divided into two genomically distinct groups based on DNA-DNA hybridization studies. One group contains the species *L. murrayi* and *L. grayi*, considered nonpathogenic. The second group contains five species: the nonhemolytic species *L. innocua* and *L. welshimeri* and the hemolytic species *L. monocytogenes, L. seeligeri*, and *L. ivanovii. L. ivanovii* is pathogenic primarily in animals, and the vast majority of both human and animal disease is due to *L. monocytogenes*.

Subtyping of *L. monocytogenes* isolates for epidemiologic purposes has been attempted using heat-stable somatic O and heat-labile flagellar H antigens, phage typing, ribotyping, and multilocus enzyme electrophoresis. Electrophoretic typing demonstrates the clonal structure of populations of *L. monocytogenes* as well as the sharing of populations between human and animal sources.

Selected biochemical tests together with the demonstration of **tumbling motility, umbrella-type formation** below the surface in semisolid medium, hemolysis, and a typical cyclic adenosine monophosphate (cAMP) test are usually sufficient to

establish a presumptive identification of *L. monocytogenes*.

Epidemiology.

L. monocytogenes is widespread in nature, has been isolated throughout the environment, and is associated with epizootic disease and asymptomatic carriage in more than 42 species of wild and domestic animals and 22 avian species. Epizootic disease in large animals such as sheep and cattle is associated with abortion and “circling disease,” a form of basilar meningitis. *L. monocytogenes* is isolated from sewage, silage, and soil, where it survives for more than 295 days. The overall disease rate in the United States is approximately 0.7/100,000; however, in infants it is 10/100,000 and in the elderly it is 1.4/100,000. The rate varies between states. Epidemic human listeriosis has been associated with food-borne transmission in several large outbreaks, especially associated with aged soft cheeses; improperly pasteurized milk and milk products; contaminated raw and ready-to-eat beef, pork, poultry, and packaged meats; and vegetables grown on farms where the ground is contaminated with the feces of colonized animals. The ability of *L. monocytogenes* to grow at temperatures as low as 4℃ increases the risk of transmission from aged soft cheeses and stored contaminated food. Small clusters of nosocomial person-to-person transmission have occurred in hospital nurseries and obstetric suites. Sporadic endemic listeriosis is less well characterized. Likely routes include food-borne infection, zoonotic spread, and person-to-person transmission. Zoonotic transmission with cutaneous infections occurs in veterinarians and farmers who handle sick animals.

Reported cases of listeriosis are clustered at the extremes of age. Some studies have shown higher rates in males and a seasonal predominance in the late summer and fall in the northern hemisphere. Outside the newborn period and during pregnancy, disease is usually reported in patients with underlying immunosuppression, with a 100–300 times increased risk in HIV-infected persons and in the elderly (Box 173–1).

The incubation period is defined only for common-source food-borne disease and is 21–30 days. Asymptomatic carriage and fecal excretion are reported in 1% of healthy persons and 5% of abattoir workers, but duration of excretion, when studied, is short (<1 mo).

Pathogenesis.

L. monocytogenes produces multisystem disease, particularly pyogenic meningitis. Granulomatous reactions and microabscess formation have been reported in many organs, including the liver, lungs, adrenals, kidneys, central nervous system (CNS), and, notably, the placenta. Animal models demonstrate translocation, the transfer of intraluminal organisms across intact intestinal mucosa; whether or not this occurs in humans is not known.

Studies of intracellular and intercellular spread of *L. monocytogenes* have revealed a complex pathogenesis. Four pathogenic steps are described: internalization, escape from the phagocytic vacuole, nucleation of actin filaments, and cell-to-cell spread. Genes involved in each step are known, and isogenic mutants have been shown to have reduced virulence. **Listeriolysin**, a hemolysin and the best-characterized virulence factor, probably mediates lysis of vacuoles and is responsible for the zone of hemolysis when grown on blood-containing solid media. In cell-to-cell spread, locomotion proceeds via cytochalasin-sensitive polymerization of actin filaments, which extrude the bacteria in pseudopods, which are phagocytosed by adjacent cells, necessitating escape from a double-membrane vacuole. This mechanism protects intracellular bacteria from the humoral arm of immunity and is responsible for the well-known requirement of T-cell–mediated activation of monocytes by lymphokines for clearance of infection and establishment of immunity. The role of opsonizing antibody in protecting against infection is unclear.

Clinical Manifestations.

The clinical presentation of listeriosis is highly dependent on the age of the patient and the circumstances of the infection.

LISTERIOSIS IN PREGNANCY.

Early gestational listeriosis is not well understood. *L. monocytogenes* has been grown from placental and fetal cultures of pregnancies ending in spontaneous abortion. The usual presentation in the 2nd and 3rd trimesters is a flulike illness that may result in bacteremia seeding the uterine contents. Rarely is maternal listeriosis severe, but meningitis in pregnancy has been reported. Recognition and treatment at this stage have been associated with normal pregnancy outcomes, but the fetus may not be infected even if listeriosis in the mother

Box 173-1. Types of *Listeria monocytogenes* Infections

Listeriosis in the elderly

is not treated. In other instances, placental listeriosis develops with infection of the fetus that may be associated with stillbirth or premature delivery. Delivery of an infected premature fetus is associated with 50–90% infant mortality. Disseminated disease is apparent at birth, often with a diffuse pustular rash. Infection in the mother usually resolves without specific therapy after delivery, but postpartum fever and infected lochia may occur.

NEONATAL LISTERIOSIS.

Two clinical presentations are recognized for neonatal listeriosis: early onset (<5 days, usually within 1–2 days), which is a predominantly septicemic form, and late-onset (>5 days, mean 14 days), which is a predominantly meningitic form (Table 173–1). The principal characteristics of the two presentations resemble the clinical syndromes described for group B streptococcus (Chapter 169).

Early-onset disease occurs from milder transplacental or ascending infections from the female genital tract. There is a strong association with recovery of *L. monocytogenes* from the maternal genital tract, obstetric complications, prematurity, and neonatal sepsis with multiorgan involvement without CNS localization. The mortality rate is approximately 20–30%.

The epidemiology of late-onset disease is poorly understood. Onset is usually after 5 days but before 30 days of age. Affected infants frequently are term, and the mothers are culture negative and asymptomatic. The presenting syndrome is usually of purulent meningitis, which, if adequately treated, has a mortality rate of <20%.

POSTNEONATAL INFECTIONS.

Listeriosis beyond the newborn period may rarely occur in otherwise healthy children but is most often encountered in association with underlying malignancies or immunosuppression. The clinical presentation is usually meningitis, less commonly sepsis, and rarely other CNS involvement such as cerebritis, meningoencephalitis, brain abscess, spinal cord abscess, or a focus outside the CNS such as suppurative arthritis, osteomyelitis, endocarditis, peritonitis (associated with peritoneal dialysis), or liver abscess. It is not known whether the frequent gastrointestinal signs and symptoms result from enteric infection, because the mode of acquisition is unknown.

Diagnosis.

Listeriosis should be included in the differential diagnosis of infections in pregnancy, neonatal sepsis and meningitis, and of sepsis or meningitis in older children with underlying malignancies, receiving immunosuppressive therapy, or following transplantation. The diagnosis is established by culture of *L. monocytogenes* from blood or cerebrospinal fluid (CSF). Cultures from the maternal cervix, vagina, or lochia and, if possible, placenta should be obtained when intrauterine infections lead to premature delivery or early onset neonatal sepsis. It is helpful to alert the laboratory to suspected cases so that *Listeria* isolates are not discarded as contaminating diphtheroids.

Histologic examination of the placenta is useful. Polymerase chain reaction assays detect *L. monocytogenes*, but commercial assays are not available. Serodiagnostic tests have not proved useful.

TABLE 173-1 -- **Characteristic Features of Early and Late Onset Neonatal Listeriosis**

Early Onset (<5 days)	Late Onset (=5days)

Positive maternal *Listeria* culture	Negative maternal *Listeria* culture
Obstetric complications	Uncomplicated pregnancy
Premature delivery	Term delivery
Low birthweight	Normal birthweight
Neonatal sepsis	Neonatal meningitis
Mean age at onset 1.5 days	Mean age at onset 14.2 days
Mortality rate >30%	Mortality rate <10%
	Nosocomial outbreaks

DIFFERENTIAL DIAGNOSIS.

Listeriosis is indistinguishable clinically from neonatal sepsis and meningitis due to other organisms. The presence of increased peripheral blood monocytes suggests the possibility of listeriosis. Monocytosis or lymphocytosis may be modest or striking. Beyond the neonatal period, *L. monocytogenes* CNS infection is associated with fever, headache, seizures, and signs of meningeal irritation. The brainstem characteristically may be affected. The white blood cell concentration may vary from normal to slightly elevated, and the CSF laboratory findings are variable. Polymorphonuclear leukocytes or mononuclear cells may predominate, with shifts from polymorphonuclear to mononuclear cells in sequential lumbar punctures. A low CSF glucose level that mirrors the severity of disease is usually found. The CSF protein is moderately elevated. *L. monocytogenes* is isolated from the blood in 40–75% of cases of meningitis due to the organism. Deep focal infections, such as endocarditis, osteomyelitis, and liver abscess due to *L. monocytogenes* are also indistinguishable clinically from the more common organisms associated with these sites. Cutaneous infections should be suspected in patients with a history of contact with animals, especially products of conception.

Treatment.

The emergence of multiple antibiotic resistance makes routine susceptibility testing of isolates mandatory. Ampicillin alone (100–200?mg/kg/24?hr divided q 6?hr IV; 200–400?mg/ kg/24?hr divided q 6?hr IV if meningitis is present) or in combination with an aminoglycoside (5–7.5?mg/kg/24?hr divided q 8?hr IV) is the therapy of choice. Special attention to dosing is required for neonates, who require longer dosing intervals due to the longer half-lives of the antibiotics. Combination therapy is recommended for severe infections. Isolates usually demonstrate tolerance, with the minimum bactericidal concentration =32 times the minimum inhibitory concentration, to ampicillin as well as penicillin, erythromycin, and tetracycline. Addition of gentamicin lowers the minimum bactericidal concentration. *L. monocytogenes* is not susceptible to the cephalosporins, including third-generation cephalosporins. If these agents are used for empirical therapy for neonatal sepsis or meningitis in a newborn, it is essential to add ampicillin for possible *L. monocytogenes* infection. Vancomycin, or vancomycin and an aminoglycoside, is an alternative, as are trimethoprim-sulfamethoxazole and erythromycin. The duration of therapy is usually 2–3 wk with 3 wk recommended for immunocompromised persons and meningitis. A longer course is needed for endocarditis brain abscess or osteomyelitis.

Prognosis.

Early gestational listeriosis may be associated with abortion or stillbirth, although maternal infection with sparing of the fetus has been reported. No convincing evidence shows that *L. monocytogenes* is associated with repeated spontaneous abortions in humans. The mortality rate is >50% for premature infants infected in utero, 30% for early onset neonatal sepsis, 15% for late-onset neonatal meningitis, and <10% in older children with prompt institution of appropriate antimicrobial therapy. Mental retardation, hydrocephalus, and other CNS sequelae are reported in survivors of *Listeria* meningitis.

Prevention.

Listeriosis can be prevented by pasteurization and thorough cooking of foods. Irradiation of meat products may also be beneficial. Consumption of unpasteurized or improperly processed dairy products, especially aged soft cheeses, uncooked and precooked meat products that have been stored at 4°C for extended periods, and unwashed vegetables should be avoided. This is particularly important during pregnancy and for immunocompromised persons. Infected domestic animals should be avoided when possible. Careful handwashing is essential to prevent nosocomial spread within obstetric and neonatal units. Immunocompromised patients given prophylaxis with trimethoprim-sulfamethoxazole are protected from *Listeria* infections.

Chapter 174 - *Actinomyces*

Richard F. Jacobs
Gordon E. Schutze

Actinomyces are slow-growing, gram-positive bacteria that are part of the normal oral flora in humans. Their filamentous structure gives them a fungus-like appearance. Infection caused by these bacteria is termed **actinomycosis**, which is a chronic, granulomatous, suppurative disease characterized by peripheral spread with extension to contiguous tissue in the formation of numerous draining sinus tracts. These infections usually involve the cervicofacial, thoracic, abdominal, or pelvic regions.

Etiology.

Actinomyces israelii is the predominant organism causing actinomycoses in humans. Other implicated species, in order of importance, include *Propionibacterium propionicum* (originally described as *A. propionicum), A. odontolyticus, A. meyeri, A. naeslundii, A. viscosus, A. europa, A. turicensis*, and *A. radingae. Arcanobacterium pyogenes* (previously in the *Actinomyces* genus) also causes human actinomycosis. *Actinobacillus actinomycetemcomitans* is a fastidious, gram-negative rod that frequently complicates actinomycosis caused by *A. israelii*. In addition to being associated with actinomycosis, it is part of the oral flora and has been implicated as a pathogen in periodontal disease. Other bacterial species isolated concomitantly in human actinomycosis are *Eikenella corrodens, Fusobacterium, Bacteroides, Capnocytophaga, Staphylococcus, Streptococcus*, and Enterobacteriaceae.

Actinomyces are non–spore-forming gram-positive, facultative, or strict anaerobes with a variable morphology and are members of the **HACEK group**, which also includes *Haemophilus aphrophilus, Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*. The irregular morphology ranges from diphtheroid to mycelial. *Actinomyces* organisms are found in clinical specimens, such as sputum, purulent exudates, and tissues obtained surgically or at necropsy. Staining of crushed tissue specimens rinsed with sterile saline or purulent exudate stained by Gram or acid-fast procedures can reveal organisms within the classic **sulfur granules**. Cultures on brain-heart infusion agar incubated at 37°C anaerobically (95% nitrogen and 5% carbon dioxide) and a separate set incubated aerobically reveal organisms within the lines of streak at 24–48?hr. *A. israelii* colonies appear as loose masses of delicate branching filaments with a characteristic spider-like growth. Colonies of *A.*

naeslundii, A. viscosus, and *P. propionicus* may have similar growth characteristics. Owing to the similarity in growth characteristics from colony morphology, various biochemical tests are performed to identify the specific organism.

Epidemiology.

Actinomycosis occurs worldwide without relation to age, sex, race, season, or occupation. In a review of 85 cases of actinomycosis, 27% were in persons <20 yr of age, with 7% of the patients <10 yr of age. The youngest patient in this series was 28 days old. The source of human infection is almost always endogenous flora. Although actinomycosis is usually not an opportunistic infection, disease has been described in patients receiving corticosteroids and those with leukemia, renal failure, congenital immunodeficiency diseases, and HIV infection. In one study, antecedent disease and surgery predisposed 81 of 181 subjects to infection.

Actinomycosis, even in closed infections, is usually part of a polymicrobial infection involving mixed bacteria. In a large study of more than 650 cases, infection with *Actinomyces* was identified in pure culture in only one case and usually was identified with other bacteria, most notably *Actinobacillus actinomycetemcomitans* and *Haemophilus aphrophilus*, as well as other local flora.

Pathogenesis.

The organism infects the host after introduction into the tissue by trauma or aspiration into the lung. It spreads locally and, rarely, hematogenously. Actinomycosis is a chronic, suppurative, scarring inflammatory process. Sites of infection show dense cellular infiltrates and suppuration that form many interconnecting abscesses and sinus tracts. This may be followed by cicatricial healing from which the organism then spreads by burrowing along fascial planes. This causes deep communicating scarred sinus tracts. Characteristic **sulfur granules** have an adherent mass of polymorphonuclear neutrophils that are attached to the radially arranged eosinophilic clubs of the granule. A fuzzy outer coat of hairlike fimbriae has been considered to contribute to failure of endodontic therapy due to *A. israelii*.

The three important sites of *Actinomyces* infection in order of frequency are cervicofacial, abdominal, and thoracic. Many less common infections occur, involving every organ in the body. Actinomycosis must be differentiated from several other chronic inflammatory diseases, including tuberculosis, mycotic infections, *Yersinia enterocolitica* "pseudoappendicitis," appendicitis, amebiasis, hepatic abscess, osteomyelitis, nocardiosis, and other chronic bacterial infections. In addition to introduction at wound sites, another route is through use of intrauterine devices (IUDs), which permit the development of pelvic and gastrointestinal actinomycosis. Pulmonary actinomycosis occurs after inhalation or aspiration of organisms, introduction of a colonized foreign body, or spread from an existing cervicofacial or abdominal actinomycotic infection. These masslike lesions may present as a tumor, necessitating invasive approaches for differentiation.

Clinical Manifestations.

The three major forms of actinomycosis—cervicofacial, abdominal and pelvic, and pulmonary infections—arise by different routes but may predispose to other forms of the disease. The diagnosis of actinomycosis in children suggests an underlying immunodeficiency disease state, especially chronic granulomatous disease.

CERVICOFACIAL ACTINOMYCOSIS.

In cervicofacial actinomycosis, the organisms enter the tissues after trauma that disrupts the mucous membranes of the mouth or pharynx or by way of caries. Patients with this type of actinomycosis often have a history of oral surgery, dental procedures, or trauma to the mouth. Cervicofacial actinomycosis usually presents as a painless, slow growing, hard mass that can produce cutaneous fistulas, a condition commonly known as **lumpy jaw** (Fig. 174–1). Less frequently, cervicofacial actinomycosis can present with findings suggestive of an acute pyogenic infection with an acute, tender, fluctuant mass with trismus, firm swelling, and fistulas with drainage containing the characteristic

---

Figure 174-1 A 2-yr-old boy with HIV infection who has cervicofacial actinomycosis and a chronic draining fistula.

sulfur granules. Bone is not involved early in the disease, but periostitis, mandibular osteomyelitis, or perimandibular abscess may later develop. Infection may spread by way of sinus tracts to the cranial bones, which may give rise to meningitis. The ability of *Actinomyces* to burrow through tissue planes and even bone is a key differentiating point between actinomycosis and nocardiosis. The cervicofacial type of actinomycosis has the best prognosis, and is usually cured with surgical debridement and excision as an adjunct to appropriate antibiotic therapy.

ABDOMINAL AND PELVIC ACTINOMYCOSIS.

Because abdominal actinomycosis also is the result of disruption of the mucosa of the gastrointestinal tract, patients may present with a history of gastrointestinal surgery, diverticulitis, or appendicitis. This disease usually develops as a result of an acute gastrointestinal perforation or after abdominal trauma. Of all the forms of actinomycosis, a delayed diagnosis is typical for abdominal or pelvic disease. Gastrointestinal disease occurs as appendicitis in 25% of cases but can be manifested as various ulcerative diseases. Infection classically appears after appendectomy as a hard, irregular mass in the ileocecal area that softens and then drains to the outside through a fistula. Hepatic involvement has been described in approximately 15% of abdominal actinomycosis cases as solitary or multiple liver abscesses or in a miliary pattern. The clinical course is indolent, with chills, fever, night sweats, and weight loss, and is similar to the presentation of tuberculous peritonitis. Extension from this focus is usually by direct continuity or, rarely, hematogenously to involve any tissue or organ, including muscle, spleen, kidneys, fallopian tubes, ovaries, uterus, testes, bladder, or rectum.

Women wearing IUDs are at risk for developing pelvic actinomycosis. They may present with vaginal discharge, pelvic pain, abdominal pain, menorrhagia, fever,

pelvic mass, a history of pelvic inflammatory disease, and/or a history of prolonged IUD use. The risk is more significant if the IUD has been in place for >2–3 yr.

PULMONARY ACTINOMYCOSIS.

Neither the clinical nor the radiographic presentation of pulmonary actinomycosis is specific. Pulmonary actinomycosis may present as an endobronchial infection, a tumor-like lesion, diffuse pneumonia, or a pleural effusion. Principal symptoms include fever, productive cough, chest pain, and weight loss. Infection frequently dissects along tissue planes and may extend through the chest wall or diaphragm, producing numerous sinuses. These characteristic sinus tracts contain small abscesses and purulent drainage. Other complications include bony destruction of adjacent ribs, sternum, and vertebral bodies. Pyogenic mediastinitis has been attributed to *A. odontolyticus* in lung transplant recipients. Multiple lobe involvement is occasionally found in the lung. Associated conditions, such as dental caries, aspiration, inhalation injury, introduction of a colonized foreign body, or pre-existing cervicofacial or abdominal disease, should heighten the index of suspicion. Accurate diagnosis can be more difficult with the propensity of *Actinomyces* to infect pre-existing pulmonary cavities. Diagnosis can be confirmed by examining purulent sinus tract drainage for sulfur granules, and by appropriate cultures. The presence of *Actinomyces* in sputum or bronchoscopy specimens is hampered because these organisms are normal oral flora. The differential diagnosis of pulmonary actinomycosis includes lung abscess and tuberculosis.

OTHER FORMS.

Laryngeal actinomycosis rarely has been reported in older teenagers. Colonization of the oropharynx with these organisms may be involved in the development of obstructive tonsillar hypertrophy. *A. pyogenes* only rarely has been implicated as a cause of human infection, but there are reported cases of septicemia, endocarditis, meningitis, arthritis, empyema, pneumonia, otitis media, cystitis, mastoiditis, appendicitis, and cutaneous infection. *A. actinomycetemcomitans* is a pathogen in at least 30% of actinomycotic infections. Failure to recognize this organism and treat it adequately has resulted in clinical relapse and deterioration in infected patients with actinomycosis. Severe forms of periodontitis, particularly localized juvenile periodontitis, are associated with *Actinomyces*, especially in children 10–19 yr of age. Like other HACEK organisms, *Actinomyces* has a propensity for infecting heart valves and results in an insidious presentation of endocarditis, with fever occurring in <50% of cases.

Diagnosis.

Microscopic examination with appropriate stains and culture of purulent drainage from fistulas, abscesses, draining sinus tracts, bronchoalveolar lavage, and sputum can reveal *Actinomyces* as an irregular, non–spore-forming, non–acid-fast, non-motile gram-positive bacillus. Inoculation of anaerobic and aerobic cultures enhances the yield on microbiologic cultures. An abdominal CT scan can be helpful in identifying the presence of a contrast-enhancing multicystic lesion that can be approached by CT-guided needle biopsy and culture.

Treatment.

The mainstay of treatment for actinomycosis is prolonged antibiotic therapy and an appropriate surgical approach to sinus tracts and abscesses. Prompt use of antibiotics results in a high cure rate. Actinomycosis is treated with penicillin (250,000?U/kg/24?hr divided q 4?hr IV). Other appropriate antibiotics include tetracycline, clindamycin, chloramphenicol, and carbapenems. Although controversy still exists about the dosage and duration of therapy, appropriate therapy usually includes parenteral antibiotics for 2–6 wk followed by oral antibiotics for 3–12 mo. The oral antibiotic of choice is penicillin V (100?mg/kg/24?hr divided q 6?hr PO). Although most *A. israelii* strains are sensitive to penicillin with minimum inhibitory concentrations of 0.03–0.5?mg/mL, some resistant strains have been identified. Antibiotic susceptibility testing should be performed on all isolates from patients with significant disease or who are immunocompromised. Hepatic abscesses or other deep tissue infections should be treated for 6–12 mo. Large abscesses usually require surgical excision. Removal of chronically infected tonsils and treatment of pyorrhea or caries may eliminate possible sources of infection. Generally, the prognosis is excellent with adequate therapy and early diagnosis.

Because co-infection with *A. actinomycetemcomitans* does occur regularly, it is important to consider covering this organism empirically, especially in the critically ill patient. *A. actinomycetemcomitans* is susceptible to newer cephalosporins, rifampin, trimethoprim-sulfamethoxazole, aminoglycosides, ciprofloxacin, tetracycline, and azithromycin. It is susceptible to penicillin and ampicillin in vitro, but test results do not correlate necessarily

with clinical outcome. In some patients with periodontitis associated with this organism, a combination of mechanical periodontal treatment with metronidazole plus amoxicillin is effective for subgingival suppression. **REFERENCES**

Chapter 175 - *Nocardia*

Richard F. Jacobs
Gordon E. Schutze

Nocardiosis is an acute, subacute, or chronic suppurative infection with a tendency for remissions and exacerbations that cause localized and disseminated disease in children and adults. Recently, larger series of primary cutaneous nocardiosis in children have been reported from the southern United States.

Etiology.

Nocardia is a member of the order Actinomycetales, which includes gram-positive filamentous bacteria such as *Actinomyces, Streptomyces*, and mycobacteria. Soil and decaying vegetable matter are their natural habitat. Numerous taxonomic studies have established the heterogeneity of the species *Nocardia asteroides*, the most common cause of human nocardiosis, and have led to the description of ***N. asteroides complex***. *N. brasiliensis* is the second most frequent etiologic agent of human nocardiosis. Current methods of recognition of *N. asteroides* in the clinical laboratory include microscopic and colonial morphology, resistance to lysozyme, and inability to hydrolyze casein, tyrosine, xanthine, and hypoxanthine. *N. asteroides, N. farcinica, N. otidis-caviarum*, and *N. nova* share similar features and have contributed to the apparent heterogeneity of *N. asteroides*. New identification and rapid diagnostic schemes use molecular typing and identification of preformed enzymes.

In 1988, a susceptibility study of 78 clinical isolates of the *N. asteroides* complex from the United States found that 95% of strains exhibited one of five antibiotic resistance patterns. The most common group, occurring in 35% of isolates, was resistant to ampicillin but susceptible to the broad-spectrum cephalosporins and imipenem. Approximately 20% of isolates, including essentially all isolates in the *N. asteroides* complex, were resistant to cefotaxime, ceftriaxone, and cefamandole, which were subsequently identified as *N. farcinica*. Approximately 20% of the strains were susceptible to ampicillin and erythromycin, which were subsequently identified as *N. nova*. The remaining types had susceptibility patterns that included resistance to broad-spectrum cephalosporins and susceptibility to ampicillin and carbenicillin, but intermediate susceptibility to imipenem. The most active parenteral agents were amikacin (95%), imipenem (88%), ceftriaxone (82%), and cefotaxime (82%). The most active oral agents were sulfonamides (100%), minocycline (100%), and

ampicillin (40%).

Systemic nocardiosis is caused most frequently by the bacteria in the *N. asteroides* complex. *N. brasiliensis* is the principal cause of localized nocardial cellulitis and lymphadenitis in immunocompetent children but also causes a form of pulmonary and systemic disease, especially in immunocompromised patients. *Actinomadura madurae* (**Madura foot**), *N. farcinica, N. nova*, and *N. transvalensis* are also causes of human disease. *N. asteroides* complex includes the most common agents of systemic nocardiosis in the United States, whereas *N. brasiliensis* is found more commonly in the southern United States, Central America, South America, and Asia. These agents are similar morphologically and can be distinguished only by biochemical and serologic procedures.

Epidemiology.

Nocardiosis was once thought to be a rare cause of human disease but is now being recognized more frequently, having been diagnosed in individuals ranging from 4 wk–82 yr of age. Almost all of the patients have one or more severe underlying diseases, usually accompanied by compromised cellular immunity from corticosteroids, primary immunodeficiency (chronic granulomatous disease), organ transplantation, cancer chemotherapy, or HIV infection. HIV-infected patients are at increased risk, although nocardiosis is not considered an AIDS-defining infection. *Nocardia* infections in bone marrow transplant recipients have been associated with a high rate of invasive fungal infection and a lack of protection by trimethoprim-sulfamethoxazole prophylaxis.

Soil is the natural habitat of *Nocardia*, which has been isolated worldwide. The organism is inhaled in aerosolized dust and causes pulmonary infection, with widespread dissemination in susceptible hosts, and it can be transmitted by direct skin inoculation. Cases of nocardiosis following arthropod bite and cat bite have been reported in recent years. Although communicability from human to human has not been proved to be common, a description of human-to-human transmission of *N. farcinica* resulting in sternal wound infections in patients undergoing open heart surgery has raised concern about *Nocardia* as a nosocomial pathogen.

Pathogenesis.

N. asteroides complex and *N. brasiliensis* organisms are obligate aerobes and grow on ordinary culture media. These organisms are sensitive to various antibiotics; thus, media containing these specific drugs do not support growth. Many isolates of *Nocardia* are thermophilic and can grow at temperatures up to 50°C; however, best growth is achieved at 37°C. At 25°C, the organisms grow very slowly. Colonies appear within 1–2 wk on brain-heart infusion agar and Lowenstein-Jensen media, usually as waxy, folded, or heaped colonies at the edges. With further incubation, these colonies develop aerial hyphae that tend to give them a white, chalky appearance. Classifications of species of *Nocardia* are based on physiologic reactions with various substrates and antibiotic susceptibility testing. An isolated 55-kd protein that has apparent specificity for *N. asteroides* complex is used in an enzyme immunoassay. In biopsy specimens or clinical body fluids using modified Kinyoun acid-fast staining, *Nocardia* demonstrates fragmented bacilli with stain concentrated in a **beaded pattern** along portions of the branching filaments.

Clinical Manifestations.

Pulmonary nocardiosis accounts for 75% of cases, which almost all occur in immunocompromised patients or patients with underlying pulmonary disease. Demonstration of tissue invasion is important for identifying active infection because the organism occasionally exists as a respiratory saprophyte (Fig. 175–1). Clinical manifestations include pneumonia and necrotizing pneumonia with single or numerous abscesses. Diagnosis is established in one third of cases in adults by sputum analysis and culture. Bronchoalveolar lavage or lung biopsy may be required to establish the diagnosis in the remaining two thirds of adults and in children. The mortality with nocardiosis is >50% in immunocompromised patients with disseminated disease but may be lower with earlier diagnosis.

Metastatic lesions may occur anywhere in the body, but the brain is the most common secondary site and is affected in 15–40% of cases. Brain lesions may be numerous or single. Brain abscess is the most common presentation, with meningitis the second most common, as manifested by pleocytosis (with a lymphocytic or neutrophilic predominance), elevated cerebrospinal fluid protein, and hypoglycorrhachia. Persistent neutrophilic meningitis with sterile cultures is classic for central nervous system (CNS) infection. The onset of CNS infection may be gradual or sudden and includes manifestations varying from headache to coma. Cranial CT or MRI is recommended in all immunocompromised patients with pulmonary nocardiosis, even when asymptomatic, because of the frequency of CNS involvement, and should be considered in all patients with pulmonary nocardiosis.

The skin is the third most commonly involved organ. Renal nocardiosis is the fourth most common site, presenting with dysuria, hematuria, or pyuria. Lesions may extend from the cortex into the medulla. Gastrointestinal involvement may also be associated, with nausea, vomiting, diarrhea, abdominal distention, and melena. Infection may metastasize to skin, pericardium, myocardium, spleen, liver, or adrenal glands; bone involvement is rare. Almost all of the involved organs have several abscesses, but in contrast to actinomycosis, granules are rarely found. Keratitis due to *N. farcinica* has been associated with the use of semipermeable rigid contact lenses.

Figure 175-1 A 2-yr-old female with multiple pustules on the dorsum of the right foot caused by *Nocardia brasiliensis*. (Photograph courtesy of Jaime E. Fergie, MD.)

Diagnosis.

Laboratory diagnosis of nocardiosis requires direct examination of clinical material for characteristic gram-positive, acid-fast organisms and isolation by culture methods. Smears of clinical material are Gram stained or stained by the modified Kinyoun acid-fast stain. *N. asteroides* complex and *N. brasiliensis* appear as

delicately branched gram-positive coccoid to bacillary structures that tend to fragment. In properly stained and decolorized acid-fast smears, the organisms may appear as fragmented bacilli with the stain concentrated in a beaded pattern along the portions of the filaments. Antibody titers to the 55-kd *Nocardia* protein of =1:256 appear sensitive and specific for diagnosis and have also been used to monitor response to medical treatment.

Treatment.

Sulfonamides are the drugs of choice. Sulfisoxazole (120–150?mg/kg/24?hr divided q 6?hr PO), or trisulfapyrimidines, for 3–6 mo is standard therapy. For severe infections, based on susceptibility testing, amikacin (15–30?mg/kg/24?hr divided q 8?hr IV or IM) as a single agent or in combination with a ß-lactam antibiotic (e.g., a third-generation cephalosporin or carbapenem) can be used. In addition, and based on in vitro susceptibility testing for specific *N. asteroides* complex isolates, alternative drug combinations may include erythromycin and newer macrolides (azithromycin and clarithromycin), carbapenems, streptomycin, minocycline, quinolones, and third-generation cephalosporins. Clinical trials have shown ampicillin or amoxicillin-clavulanate to be effective in *N. brasiliensis* infections. Antibiotic resistance has become an important issue in many *Nocardia* infections, with resistance to trimethoprim-sulfamethoxazole, streptomycin, and ampicillin reported. Surgical drainage of abscesses is important. Relapses of *Nocardia* have occurred in patients treated for <3 mo. Patients with AIDS probably should be treated indefinitely.

Prognosis.

Despite adequate therapy, the overall mortality is >50%, which may be secondary to a delay in diagnosis or to the debilitated state of patients with severely compromised host defenses.

Section 3 - *Gram-Negative Bacterial Infections*

Chapter 176 - *Neisseria meningitidis* (Meningococcus)

Charles R. Woods

Meningococcal disease, first described by Vieusseaux in 1805 as epidemic cerebrospinal fever, remains a significant health problem worldwide. Most persons with meningococcal infections in developed nations survive, but healthy patients continue to succumb to fulminant disease despite advances in modern critical care medicine. Such cases, especially in the context of community outbreaks of meningococcal infection, create public fear and are not soon forgotten.

Etiology.

Neisseria meningitidis is a gram-negative diplococcus. In Gram-stained specimens the microbes appear as kidney-shaped pairs with adjacent sides flattened. In most persons, meningococci are commensal colonizers of the nasopharynx. Humans are the only natural reservoir. *N. meningitidis* is fastidious. Growth is facilitated in a moist environment at 35–37°C in a 5–10% carbon dioxide atmosphere. Growth is readily supported by chocolate, blood, and Mueller-Hinton media used routinely in clinical laboratories. On solid media, colonies are transparent, nonpigmented, and nonhemolytic. *N. meningitidis* is identified by its ability to ferment glucose and maltose, but not sucrose or lactose. Indole and hydrogen sulfide are not formed. Meningococci are oxidase-positive due to a cytochrome oxidase in the cell wall and produce superoxide dismutase.

The meningococcal cell wall has lipid A–containing lipo-oligosaccharides (LOS; i.e., endotoxin) covered by a polysaccharide capsule. Antigenic variation of the capsule has led to recognition of 13 serogroups. The vast majority of meningococcal disease worldwide is caused by serogroups A, B, C, W135, and Y. LOS and several protein families (porin, opacity-associated protein [Opa]) found in the outer membrane complex are used to serotype strains within serogroups.

Epidemiology.

Meningococcal infection occurs as endemic disease punctuated by outbreaks of cases that are clustered temporally and geographically. Prevalence of nasopharyngeal carriage typically is 5–10%, but higher rates can be seen among children in daycare centers and in conditions of crowding. Carriage rates can approach 100% in closed populations during epidemics. In the United States, the incidence of reported meningococcal disease ranged from 0.8–1.3/100,000 population during the 1990s, with 2100–3500 cases/yr. Invasive disease is most common among young children, with rates of 9 cases/100,000 population in the 1st year of life and >25 cases/100,000 population during the 1st 4 mo of life.

There is a slight male predominance among cases (55%). Almost 50% of cases occur in children <2 yr of age, with 25% of cases occurring in persons 30 yr of age or older. Recently, higher rates among persons 15–19 yr of age have been observed than occur among younger adolescents and older adults. College students, especially freshmen living in dormitories, are at approximately twofold to eightfold higher risk than noncollegiate peers. Viral infections, especially influenza, smoking and smoke exposure, crowded living conditions, underlying chronic diseases, and low socioeconomic status, are associated with higher risk for meningococcal infection.

Meningitis is present in 58% of cases. *N. meningitidis* is isolated from blood in about two thirds of cases, from cerebrospinal fluid (CSF) in half, and joint fluid in 1%. Serogroups B and C each account for nearly half of cases among young children in developed countries. Cases caused by serogroup Y strains increased during the 1990s, predominantly among adolescents and adults, such that serogroups B, C, and Y now each account for about one third of cases in these age groups.

Endemic disease is caused by heterogeneous meningococcal strains. Analyses with multilocus enzyme electrophoresis and several genotyping methods have shown that outbreaks are caused by single strains (clones). Transcontinental spread of epidemic clones is well documented. In the United States, there were 26 local outbreaks from 1994–1996, compared with six outbreaks from 1980–1989. Outbreaks are defined as three or more cases in a 3-mo period in the same community, such that the attack rate exceeds 10 cases/100,000 persons. Elementary and secondary school outbreaks can occur. The Pacific Northwest recently has experienced increased endemic serogroup B disease, especially among 15–19 year old persons.

Meningococcal disease, particularly group A, remains a major problem in much of the developing world. Many areas, such as in China and Africa, have endemic rates of 10–25/100,000 persons and major periodic epidemics (100–500/100,000). Endemic disease is most common among young children, whereas epidemic disease typically involves older children, adolescents, and young adults. Crowded conditions increase risk of epidemic spread.

Pathogenesis.

N. meningitidis is acquired primarily by the respiratory route. Nasopharyngeal

colonization usually leads to asymptomatic colonization, which can persist for weeks to months. Invasion is rare, tends to occur soon after acquisition of new strains, and sometimes appears facilitated by concurrent viral respiratory tract infection. Meningococci (and gonococci, but not nonpathogenic *Neisseria*) produce an IgA protease that may assist in colonization of mucous membranes by cleaving the proline-rich hinge region of secretory IgA.

Meningococci adhere selectively to nonciliated epithelial cells by way of their type IV pili. Pili attach to CD46 proteins (receptors for C3b, C4b, measles, and other viruses) on the epithelial cell surface. This induces host cytoskeletal rearrangements and microvillus production that lead to endocytosis. Opa extending

from the microbial outer membrane interact with the human CD66 family of receptor molecules and facilitate adhesion and endocytosis. Microbes then traverse the cell in membrane-bound vacuoles. Meningococcal porin proteins play roles in endocytosis, intracellular survival, apoptosis of invaded cells, and escape from complement attack through binding of C4b-binding protein.

Once through the epithelium, meningococci may gain entry into the bloodstream. Serum antibody against meningococcal surface antigens, if present, can block this dissemination by initiation of complement-mediated bacterial lysis. Absence of antimeningococcal antibody is associated with development of meningococcemia. If the bacteremia is not cleared, interaction with phagocytes continues, organisms adhere to endothelial cells (with pili, Opa, and porin proteins again involved), and the complement system is further activated. Endothelial cell expression of surface adhesion molecules is influenced by LOS and capsular polysaccharide, facilitating attachment of white blood cells. Meningococcal survival is enhanced by the polysaccharide capsule, which helps resist phagocytic killing, and an iron scavenging system that can use host transferrin and lactoferrin.

The microbial-phagocyte-endothelial cell-complement interactions lead to production of multiple proinflammatory cytokines, including tumor necrosis factor a (TNFa), interleukin (IL)-1ß, IL-6, and IL-8, and activation of both the extrinsic (by way of induction of tissue factor expression on endothelial cell and monocytes) and intrinsic pathways of coagulation. The degree of activation of the complement and clotting cascades, the concentrations of circulating cytokines, and risk of fatality correlate with the concentration of meningococcal LOS in the plasma at presentation. Progression of capillary leak and disseminated intravascular coagulopathy (DIC) can lead to multiple organ system failure, septic shock, and sometimes death. Fatal cases typically have higher concentrations of TNFa and ILs than do survivors, but the causal relationship remains unclear. LOS and TNFa levels decrease rapidly once antibiotics are given, correlating with clearance of viable microbes. Activation of the complement and clotting cascades can continue well beyond this point, especially in fulminant cases.

Non-LOS antigens appear to drive the dendritic cell maturation required for initiation of the adaptive immune response. IL-12 production, driven by meningococcal LOS, creates a Th-1 response environment. Bactericidal antibodies are produced against capsular polysaccharide, outer membrane proteins, and LOS antigens. Natural immunity against *N. meningitidis* develops in most persons after repeated colonization with different serogroups or serotypes and from gastrointestinal colonization with enteric bacteria that express cross-reactive antigens. Infants also have high carriage rates of the unencapsulated, nonpathogenic neisserial strain, *N. lactamica*, which contributes to development of immunity against meningococci. Protective effects of maternally derived IgG wanes during the 1st 3 months of life, with resultant high rates of invasive disease in the 1st year of life.

Invasive meningococcal disease is associated with an acute inflammatory response. Diffuse vasculitis and DIC are common with meningococcemia. Leukocyte-rich fibrin clots are seen in small vessels, including arterioles and capillaries. The resulting focal hemorrhage and necrosis may be seen in any organ system. The heart, central nervous system, skin, mucous and serous membranes, and adrenals are affected in most fatal cases. Myocarditis occurs in >50% of patients who die of meningococcal disease. Diffuse adrenal hemorrhage without vasculitis is common during fulminant meningococcemia (i.e., Waterhouse-Friderichsen syndrome). Meningitis is characterized by acute inflammatory cells in the leptomeninges and perivascular spaces. Focal cerebritis is uncommon.

Persons with primary complement deficiency have an increased risk of developing meningococcal disease, underscoring the important role of complement in host defense against the meningococcus. Among individuals with properdin, factor D, or terminal-component deficiencies, 50–60% will develop serious bacterial infections, caused almost solely by *N. meningitidis*. Some studies suggest disease manifestations with complement deficiencies are less severe than with intact complement function, but this is not certain. Recurrent infection is more common with terminal component deficiencies than with properdin deficiency. Similar increased risk is seen with the acquired complement deficiencies that occur in patients with diseases such as nephrotic syndrome, systemic lupus erythematosus, and hepatic failure. Among persons with meningococcal infections, complement deficiencies are much more prevalent in those >5 yr of age than in younger children.

Host factors that may affect the severity of meningococcal disease include polymorphisms of IL-1, IL-1 receptor antagonist, mannose-binding lectin, and Fc receptor genes (potentially in concert with certain IL-10 alleles) and the promoter regions for the TNFa and plasminogen-activator-inhibitor-1 genes. Presence of factor V Leiden exacerbates purpura fulminans but may not affect mortality.

The group B capsule is a homopolymer of sialic acid, which is poorly immunogenic in humans due in part to its structural homology with mammalian neural cell adhesion molecules. The B capsular antigen also does not activate the alternative complement pathway in humans, which is a key part of the innate immune response essential for protection from infections in the absence of specific antibodies. This may explain in part the higher prevalence of serogroup B meningococcal disease in young children.

Clinical Manifestations.

The spectrum of meningococcal disease varies widely from fever and occult bacteremia (Chapter 162) to sepsis and shock (Chapter 163) and death. Recognized patterns of disease include bacteremia without sepsis, meningococcemia (sepsis) without meningitis, and meningitis with or without

meningococcemia. At least 80% of cases have overt clinical signs. Occult meningococcal bacteremia often presents as fever with or without associated symptoms that suggest minor viral infections. Resolution may occur without antibiotics, but some cases will develop meningitis.

Acute meningococcemia initially may mimic viral illness with pharyngitis, fever, myalgias, weakness, vomiting, diarrhea, and/or headache. A maculopapular rash can be evident before more serious signs develop. In fulminant cases, the disease progresses rapidly over hours to septic shock characterized by hypotension, DIC, acidosis, adrenal hemorrhage, renal failure, myocardial failure, and coma. Petechiae and purpura may be prominent (purpura fulminans). Meningitis may or may not be present. Concomitant suppurative arthritis, pneumonia, myocarditis, and purulent pericarditis may be present.

The most common clinical manifestation is meningococcal meningitis, which usually responds to appropriate antibiotics and supportive therapy. Headache, photophobia, lethargy, vomiting, and nuchal rigidity and other signs of meningeal irritation typically are present. Seizures and focal neurologic signs occur less frequently than in patients with meningitis caused by pneumococcus or *Haemophilus influenzae* type b. Rarely, meningoencephalitis can occur. This may be more common with serogroup A infection.

In a series of 100 children with invasive meningococcal disease, 71% presented with fever, 42% had hypotension or decreased peripheral perfusion, and 34% had emesis. Petechiae and/or purpura were present in 49%. Purpura fulminans developed in 16%. Maculopapular rashes or pustular or bullous lesions were present in 11%. Additional presenting symptoms and signs were irritability (21%), lethargy (30%), diarrhea (6%),

rhinorrhea (10%), seizure (8%), septic arthritis (8%), and nonsuppurative arthritis (6%). Radiographic evidence of pneumonia was present initially in 8%.

Uncommon manifestations of meningococcal disease include endocarditis, purulent pericarditis, pneumonia, endophthalmitis, mesenteric lymphadenitis, osteomyelitis, sinusitis, otitis media, and periorbital cellulitis. Primary purulent conjunctivitis can lead to invasive disease. Pleural effusion or empyema occurs in 15% of cases with meningococcal pneumonia. *N. meningitidis* infections of the genitourinary tract are rare, but urethritis, cervicitis, vulvovaginitis, and proctitis can occur.

Chronic meningococcemia occurs rarely and is characterized by fever, nontoxic appearance, arthralgias, headache, and a rash similar to that of disseminated gonococcal infection. Symptoms are intermittent. The mean duration of illness is 6–8 wk. Blood cultures may initially be sterile. Meningitis can develop in untreated cases.

Diagnosis.

Definitive diagnosis of meningococcal disease is established by isolation of the organism from a normally sterile body fluid such as blood, CSF, or synovial fluid. Isolation from the nasopharynx is not diagnostic for invasive disease. Blood and CSF are the usual sources of the organism. Cultures often are negative if the patient has received prior antibiotic treatment. Meningococci sometimes can be identified in culture or Gram stain of petechial or papular lesions. Bacteria occasionally are seen on Gram stain of the buffy coat layer of a spun blood sample.

In meningitis, the morphologic and clinical characteristics of CSF are those of acute bacterial meningitis (Chapter 594.1). CSF cultures sometimes are positive in patients with meningococcemia who do not have CSF pleocytosis or clinical evidence of meningitis. Gram stain–positive CSF specimens sometimes are culture-negative. Overdecolorized pneumococci in Gram stains can be mistaken for meningococci (empirical therapy should not be based on Gram stain alone).

Detection of capsular polysaccharide antigens by rapid latex agglutination tests in CSF can support the diagnosis in cases clinically consistent with meningococcal disease. These tests are most useful when results are positive in the setting of partially treated infections with negative cultures. Antigen tests using serum or urine are not helpful. Rapid antigen tests are not reliable for serogroup B strains due to cross-reactions with other bacterial species. Detection of meningococci in blood and CSF using polymerase chain reaction has been used in research laboratories and currently are used clinically in the United Kingdom. These likely will have more widespread use in the future.

Other laboratory findings include leukocytopenia or leukocytosis (often with increased percentages of neutrophils and band forms), thrombocytopenia, proteinuria, and hematuria. Elevated sedimentation rate and C-reactive protein, hypoalbuminemia, hypocalcemia, and metabolic acidosis (often with increased lactate levels) are common. Patients with DIC have decreased serum concentrations of prothrombin and fibrinogen and prolonged coagulation studies.

DIFFERENTIAL DIAGNOSIS.

Meningococcal disease can appear similar to sepsis or meningitis caused by many other gram-negative bacteria; *S. pneumoniae, S. aureus*, or group A streptococcus; Rocky Mountain spotted fever, ehrlichiosis, or epidemic typhus; and bacterial endocarditis. Viral and other etiologies of encephalitis should be considered in some cases. Autoimmune vasculitides (especially Henoch-Schönlein purpura), serum sickness, hemolytic-uremic syndrome, Kawasaki disease, idiopathic thrombocytopenic purpura, drug eruptions, and ingestion of various poisons can have features that overlap those of meningococcal infection. Infections with echoviruses (particularly types 6, 9, and 16), coxsackieviruses (primarily types A2, A4, A9, and A16), and other viruses also may have severe presentations that initially raise concerns about meningococcal infection.

The petechial or purpuric rash of meningococcemia is similar to that of other generalized vasculitides. Benign petechial rashes are common in viral and group A streptococcal infections. The nonpetechial rashes observed in some meningococcal cases may be confused with a viral exanthem.

Treatment.

For hospitalized patients, penicillin G (250,000– 400,000?U/kg/24?hr divided q 4–6?hr IV) remains the drug of choice. Cefotaxime (200?mg/kg/24?hr) or ceftriaxone (100?mg/kg/24?hr) are acceptable alternatives and generally are part of initial empiric regimens. Chloramphenicol (75–100?mg/kg/ 24?hr divided q 6?hr IV) remains effective treatment for patients who are allergic to ß-lactam antibiotics. Therapy is continued for 5–7 days.

Early treatment of meningococcal infections may prevent serious sequelae, but timely identification of such patients is difficult in the absence of skin findings. High fever and leukocytosis with increased neutrophil and band counts are common in older children and adolescents with otherwise unsuspected meningococcal infection. Empirical outpatient treatment of selected patients during meningococcal outbreaks and of nontoxic children with petechial rashes can be considered. Most of the latter will not have meningococcal infection. Blood cultures should be obtained before treatment.

Isolates of *N. meningitidis* with relative resistance to penicillin (minimal inhibitory concentration of penicillin of 0.1–1.0?µ/mL) have been reported from Europe, Africa, Canada, and the United States. Decreased susceptibility is caused, at least in part, by altered penicillin-binding protein 2. In 1991 such strains represented ~4% of isolates in the United States. This degree of penicillin resistance does not appear to impact response to therapy. Strains producing ß-lactamase remain exceedingly rare. Routine susceptibility testing of meningococcal isolates is not indicated in the United States at this time, but continued surveillance is necessary.

Optimal supportive care is essential (Chapter 57.2). Many adjunctive therapies have been attempted in severe cases. Protein C replacement holds promise for treatment of severe sepsis and DIC and is being evaluated in children. Protein C is an anticoagulant that also downregulates the inflammatory response and is depleted in DIC. Trials of HA-1A human monoclonal antibody to endotoxin and recombinant bactericidal/ permeability-increasing protein showed less benefit than expected. Other anticoagulant or fibrinolytic agents and vasodilators have been used with variable success in anecdotal reports. Combinations of such therapies may be useful in selected cases in the future, but have yet to be evaluated.

Children with severe disease who respond poorly to aggressive fluid and inotropic therapies may have adrenal insufficiency and may benefit from hydrocortisone supplementation. Extracorporeal membrane oxygenation has been used with limited success.

Complications.

Acute complications are related to the vasculitis, DIC, and hypotension of severe meningococcal disease. Focal skin infarctions often heal but can become secondarily infected (similar to burns), resulting in significant scarring and requiring skin grafting. The gangrene of extremities often seen with purpura fulminans may necessitate amputations. Adrenal hemorrhage, endophthalmitis, arthritis, endocarditis, pericarditis, myocarditis, pneumonia, lung abscess, peritonitis, and renal infarcts can occur during acute infection. Avascular necrosis of epiphyses and epiphyseal-metaphyseal defects can result from the generalized DIC and may lead to growth disturbances and late skeletal deformities.

Deafness is the most frequent neurologic sequela, occurring in 5–10% of children with meningitis in most series. Cerebral arterial or venous thrombosis with resultant cerebral infarction can occur in severe cases. Meningitis rarely is complicated by subdural effusion or empyema or by brain abscess. Other rare

neurologic sequelae include ataxia, seizures, blindness, cranial nerve palsies, hemiparesis or quadriparesis, and obstructive hydrocephalus. The latter often presents 3–4 wk after onset of illness.

Nonsuppurative complications of meningococcal disease appear to be immune complex–mediated and become apparent 4–9 days after the onset of illness. Arthritis and cutaneous vasculitis (erythema nodosum) are most common. The arthritis usually is monoarticular or oligoarticular, involves large joints, and has sterile effusions that respond to nonsteroidal anti-inflammatory agents. Long-term sequelae are uncommon. Because most patients with meningococcal meningitis become afebrile by the 7th hospital day, persistence or recrudescence of fever after 5 days of antibiotics warrants evaluation for immune complex– mediated complications.

Reactivation of latent herpes simplex virus infections (primarily herpes labialis) is common during meningococcal infection.

Prognosis.

The mortality rate for invasive meningococcal disease remains 8–13% in the United States despite modern interventions. Poor prognostic factors on presentation include hypothermia, hypotension or shock, purpura fulminans, seizures, leukopenia, thrombocytopenia (DIC), acidosis, and high circulating levels of endotoxin and TNFa. The presence of petechiae for <12?hr before admission, the presence of hyperpyrexia, and the absence of meningitis indicate rapid progression and poorer prognosis.

Screening for complement deficiency after resolution of the acute infection can be considered for any person with meningococcal infection and should be performed for older children and adolescents. Recurrent infections also can be severe.

Prevention.

Close contacts of patients with meningococcal disease are at increased risk of infection and should be carefully monitored and brought to medical attention if fever develops. Prophylaxis is indicated as soon as possible for household, daycare, and nursery school contacts and for those who have had contact with the patient's oral secretions during the 7 days before onset of illness. Prophylaxis is not routinely recommended for medical personnel except those with intimate exposure, such as

with mouth-to-mouth resuscitation, intubation, or suctioning before antibiotic therapy was begun. Children may be given rifampin (10?mg/kg orally q 12?hr for a total of four doses; maximum dose: 600?mg; 5?mg/kg/dose for infants <1 mo of age) or ceftriaxone (125?mg in a single dose IM for children <12 yr; 250?mg in a single dose IM for >12 yr of age). Ciprofloxacin (500?mg orally as a single dose) may be given for persons =18 yr. Penicillin does not eradicate nasopharyngeal carriage; patients treated with penicillin should receive prophylaxis before hospital discharge. Hospitalized patients should be placed on droplet precautions for 24?hr after initiation of effective therapy. All confirmed or probable cases of meningococcal infection must be reported to the local public health department.

VACCINE.

A quadrivalent vaccine composed of capsular polysaccharide of meningococcal groups A, C, Y, and W135 is licensed in the United States. The vaccine is immunogenic in adults but is unreliable in children younger than 2 yr. No routine immunization use is recommended in the United States at this time. Individuals with anatomic or functional asplenia or complement component deficiencies should be immunized when beyond age 2 yr of age. The vaccine may be beneficial for travelers to countries with a high incidence of meningococcal disease. It is routinely given to American military recruits. It also is used to control sustained local outbreaks of meningococcal disease caused by one of the vaccine serogroups.

College students, especially entering freshmen and those living on campus, and their parents should be informed about the increased risk (both relative and absolute) of meningococcal disease that may be incurred. Vaccine should be made available to those who request it and may be required by some colleges and states before matriculation. Vaccination provides substantial but not absolute protection against the two thirds of meningococcal disease caused by serogroups C and Y in this age group.

Polysaccharide-protein conjugate meningococcal vaccines are immunogenic in infants and are being evaluated in the United States. A group C conjugate vaccine is now being used routinely in the United Kingdom with resulting reduction in the incidence of group C disease. Immune responses to these vaccines are boostable and likely more durable than for nonconjugate vaccines.

Efforts to develop an effective serogroup B vaccine now focus largely on conserved outer membrane proteins. Strain-specific vaccines can be produced if needed for control of serogroup B outbreaks, but such single antigen vaccines are not effective against other strains in the serogroup because of the high frequency of genetic transformation and resultant antigenic variation of *N. meningitidis*.

Chapter 177 - *Neisseria gonorrhoeae* (Gonococcus)

Toni Darville

Neisseria gonorrhoeae produces various forms of **gonorrhea**, an infection of the genitourinary tract mucous membranes and rarely of the mucosa of the rectum, oropharynx, and conjunctiva. Gonorrhea transmitted by sexual contact or perinatally is second only to chlamydial infections in the number of cases reported to the Centers for Disease Control and Prevention (CDC) in the United States. This high prevalence and the development of antibiotic-resistant strains have produced significant morbidity in adolescents.

Etiology.

N. gonorrhoeae is a nonmotile, aerobic, non–spore-forming, gram-negative, intracellular diplococcus with flattened adjacent surfaces. Optimal growth occurs at 35–37°C and at pH 7.2–7.6 in an atmosphere of 3–5% carbon dioxide. The specimen should be inoculated immediately onto fresh, moist modified Thayer-Martin or specialized transport media because gonococci do not tolerate drying. Thayer-Martin medium contains antimicrobial agents that inhibit hardier normal flora present in clinical specimens that may otherwise overgrow gonococci. Presumptive

identification may be based on colony appearance, Gram stain, and production of cytochrome oxidase. Gonococci are differentiated from other *Neisseria* species by the fermentation of glucose but not maltose, sucrose, or lactose. Gram-negative diplococci are seen in infected material, often within polymorphonuclear leukocytes.

Like all gram-negative bacteria, *N. gonorrhoeae* possess a cell envelope composed of an inner cytoplasmic membrane, a middle layer of peptidoglycan, and an outer membrane. The outer membrane contains lipo-oligosaccharides (endotoxin), phospholipid, and a variety of proteins that contribute to cell adherence, tissue invasion, and resistance to host defenses. The two systems primarily used to characterize gonococcal strains are auxotyping and serotyping. **Auxotyping** is based on genetically stable requirements of strains for specific nutrients or cofactors as defined by the ability of an isolate to grow on chemically defined media. The most widely used **serotyping** system is based on porin, a trimeric outer membrane protein that makes up a substantial part of the gonococcal envelope structure. Antibodies generated to Por have been used to serotype gonococci (e.g., PorIA-4 and PorIB-12), and changes in porin proteins present in a community are believed to occur, at least in part, as a result of selective immune pressure.

Epidemiology.

N. gonorrhoeae infection occurs only in humans. The organism is shed in the exudate and secretions of infected mucosal surfaces and is transmitted through intimate contact, such as sexual contact or parturition and, rarely, by contact with fomites. Gonococcal infections in the newborn period generally are acquired during delivery. Gonorrhea is the most common sexually transmitted disease found in sexually abused children. Rarely, *N. gonorrhoeae* may be spread by sexual play among children, but the index patient is likely to be a victim of sexual abuse. Gonococcal infections in children are acquired rarely through household exposure to infected caretakers. In such cases, the possibility of sexual abuse should be seriously considered.

In the United States, the number of reported cases of gonorrhea increased steadily in the United States from 1964–1977, fluctuated through the early 1980s, increased until 1987, and since 1987 have decreased annually. Reported cases have declined from 323 cases/100,000 population in 1987 to 123 cases/100,000 population in 1996. There were 324,901 cases reported to CDC in 1997. The decline in gonorrhea prevalence may be attributed to recommendations by CDC that only highly effective antimicrobial agents be used to treat gonorrhea. The incidence of gonorrhea is highest in high-density urban areas among persons <24 yr of age who have multiple sexual partners and engage in unprotected sexual intercourse. Increases in gonorrhea prevalence have been noted recently among men who have sex with men. Risk factors include nonwhite race, homosexuality, increased number of sexual partners, prostitution, presence of other sexually transmitted diseases (STDs), unmarried status, poverty, and failure to use condoms. Techniques of auxotyping and serotyping, and more recently, molecular typing methods have been used to analyze the spread of individual strains of *N. gonorrhoeae* within a community.

Maintenance and subsequent spread of gonococcal infections in a community require a hyperendemic, high-risk core group such as prostitutes or adolescents with multiple sexual partners. This is because most persons who have gonorrhea cease sexual activity and seek care, unless economic need or other factors (e.g., drug addiction) drive persistent sexual activity. Thus, many core transmitters belong to a subset of infected persons who lack or ignore symptoms and continue to be sexually active. This underscores the importance of seeking out and treating the sexual contacts of infected persons who present for treatment.

Gonococcal infection of neonates usually results from peripartum exposure to infected exudate from the cervix of the mother. An acute infection begins 2–5 days after birth. The incidence of neonatal infection depends on the prevalence of gonococcal infection among pregnant women, prenatal screening for gonorrhea, and neonatal ophthalmic prophylaxis.

Pathogenesis.

N. gonorrhoeae infect primarily columnar epithelium; stratified squamous epithelium is relatively resistant to invasion. Mucosal invasion by gonococci results in a local inflammatory response that produces a purulent exudate consisting of polymorphonuclear leukocytes, serum, and desquamated epithelium. The gonococcal lipo-oligosaccharide (endotoxin) exhibits direct cytotoxicity, causing ciliastasis and sloughing of ciliated epithelial cells. Once the gonococcus traverses the mucosal barrier, the lipo-oligosaccharide binds bactericidal IgM antibody and serum complement, causing an acute inflammatory response in the subepithelial space. Tumor necrosis factor and other cytokines are thought to mediate the cytotoxicity of gonococcal infections.

Gonococci may ascend the urogenital tract, causing urethritis or epididymitis in postpubertal males, and causing acute endometritis, salpingitis, and peritonitis, which are collectively termed **acute pelvic inflammatory disease (PID),** in postpubertal females. **Perihepatitis (Fitz-Hugh-Curtis syndrome)** follows dissemination through the peritoneum from the fallopian tubes to the liver capsule. Gonococci that invade the lymphatics and blood vessels may lead to inguinal lymphadenopathy; to perineal, perianal, ischiorectal, and periprostatic abscesses; and to **disseminated gonococcal infection (DGI)**.

Several gonococcal virulence and host immune factors are involved in the penetration of the mucosal barrier and subsequent manifestations of local and systemic infection. Selective pressure from different mucosal environments probably leads to changes in the outer membrane of the organism, including expression of variants of pili, opacity (Opa) proteins (formerly protein II), and lipo-oligosaccharides. These changes may enhance gonococcal attachment, invasion, replication, and evasion of the host's immune response.

For infection to occur, the gonococcus must first attach to host cells. A gonococcal IgA protease inactivates IgA1 by cleaving the molecule in the hinge region and may be an important factor in colonization or invasion of host mucosal surfaces. Gonococci adhere to the microvilli of nonciliated epithelial cells by hairlike protein structures (pili) that extend from the cell wall. Pili are thought to protect the gonococcus from phagocytosis and complement-mediated killing. Pili undergo high-frequency antigenic variation that may aid in the organism's escape from the host immune response and may provide specific ligands for different cell receptors. Opa proteins, most of which confer an opaque appearance to colonies, are also thought to function as ligands to facilitate binding to human cells. Gonococci that express certain Opa proteins adhere and are phagocytosed by human neutrophils in the absence of serum.

Other phenotypic changes that occur in response to environmental stresses allow gonococci to establish infection. Examples include iron-repressible proteins for binding transferrin or lactoferrin, anaerobically expressed proteins, and synthesis of proteins mediated by contact with epithelial cells. Gonococci may grow in vivo under anaerobic conditions or in an environment with relative lack of iron.

Approximately 24?hr after attachment, the epithelial cell surface invaginates and surrounds the gonococcus in a phagocytic vacuole. This phenomenon is thought to be mediated by the gonococcal outer membrane protein I inserting into the host cell and causing alterations in membrane permeability. Subsequently, phagocytic vacuoles begin releasing gonococci into the subepithelial space by means of exocytosis. Viable organisms may then cause local disease (i.e., salpingitis) or disseminate through the bloodstream or lymphatics.

Serum IgG and IgM directed against gonococcal proteins and lipo-oligosaccharides lead to complement-mediated bacterial lysis. Stable serum resistance to this bactericidal antibody probably results from a particular type of porin protein expressed in gonococci (most contain Por1A), and these strains are often the cause of disseminated disease. *N. gonorrhoeae* differentially subvert the effectiveness of complement and alter the inflammatory responses elicited in human infection. Isolates associated with DGI typically resist killing by normal serum (are serum-resistant), inactivate more C3b, generate less C5a, and result in less inflammation at local sites. PID isolates are serum-sensitive, inactivate less C3b, generate more C5a, and result in more inflammation at local sites. IgG antibody directed against gonococcal reduction modifiable protein (Rmp) blocks complement-mediated killing of *N. gonorrhoeae.* Anti-Rmp blocking antibodies may harbor specificity for outer membrane protein sequences shared with other neisserial species or Enterobacteriaceae or may be directed against unique Rmp upstream cysteine loop specific sequences, or both. Preexisting antibodies directed against Rmp facilitate transmission of gonococcal infection to exposed women; Rmp is highly conserved in *N. gonorrhoeae* and the blocking of mucosal defenses may be one of its functions. Gonococcal adaptation also appears to be important in the evasion of killing by neutrophils. Examples include sialylation of lipo-oligosaccharides, increases in catalase production, and changes in the expression of surface proteins.

Host factors may influence the incidence and manifestations of gonococcal infection. Prepubertal girls are susceptible to vulvovaginitis and, rarely, experience salpingitis. *N. gonorrhoeae* infects noncornified epithelium, and the thin noncornified vaginal epithelium and alkaline pH of the vaginal mucin predispose this age group to infection of the lower genital tract. Estrogen-induced cornification of the vaginal epithelium in neonates and mature females resists infection. Postpubertal females are more susceptible to salpingitis, especially during menses, when diminished bactericidal activity of the cervical mucus and reflux of blood from the uterine cavity into the fallopian tubes facilitate passage of gonococci into the upper reproductive tract.

Populations at risk for DGI include asymptomatic carriers; neonates; menstruating, pregnant, and postpartum women; homosexuals; and immunocompromised hosts. The asymptomatic carrier state implies failure of the host immune system to recognize the gonococcus as a pathogen, the capacity of the gonococcus to avoid being killed, or both. Pharyngeal colonization has been proposed as a risk factor for DGI. The high rate of asymptomatic infection in pharyngeal gonorrhea may account for this phenomenon. Women are at greater risk for developing DGI during menstruation, pregnancy, and postpartum, presumably because of the maximal endocervical shedding and decreased peroxidase bactericidal activity of the cervical mucus during these periods. A lack of neonatal bactericidal IgM antibody is thought

to account for a neonate's increased susceptibility to DGI. Persons with terminal complement component deficiencies (C5-C9) are at considerable risk of developing recurrent episodes of DGI.

Clinical Manifestations.

Gonorrhea is manifested by a spectrum of clinical presentations, from asymptomatic carriage to the characteristic localized urogenital infections, to disseminated systemic infection.

ASYMPTOMATIC GONORRHEA.

The incidence of this form of gonorrhea in children has not been ascertained. Gonococci have been isolated from the oropharynx of young children who have been abused sexually by male contacts; oropharyngeal symptoms are usually absent. Most genital tract infections produce symptoms in children. However, as many as 80% of sexually mature females with urogenital gonorrhea infections are asymptomatic in settings in which most infections are detected through screening or other case-finding efforts; asymptomatic rectal carriage of *N. gonorrhoeae* has been documented in 40–60% of females with urogenital infection. Most persons with positive rectal cultures are asymptomatic. Most pharyngeal gonococcal infections are asymptomatic. The importance of documenting pharyngeal infection is debated. Most cases resolve spontaneously, transmission from the pharynx to other patients is uncommon, and the pharynx is rarely the only site of infection. On the other hand, pharyngeal infection is sometimes symptomatic and may occasionally be the source of transmission to sexual partners or systemic dissemination.

UNCOMPLICATED GONORRHEA.

Genital gonorrhea has an incubation period of 2–5 days in men and 5–10 days in women. Primary infection develops in the urethra of males, the vulva and vagina of prepubertal females, and the cervix of postpubertal females.

Urethritis is usually characterized by a purulent discharge and by dysuria without urgency or frequency. Untreated urethritis in males resolves spontaneously in several weeks or may be complicated by epididymitis, penile edema, lymphangitis, prostatitis, or seminal vesiculitis. Gram-negative intracellular diplococci are found in the discharge.

In prepubertal females, vulvovaginitis usually is characterized by a purulent vaginal discharge with a swollen, erythematous, tender, and excoriated vulva. Dysuria may occur. In postpubertal females, symptomatic gonococcal cervicitis and urethritis are characterized by purulent discharge, suprapubic pain, dysuria, intermenstrual bleeding, and dyspareunia. The cervix may be inflamed and tender. In urogenital gonorrhea limited to the lower genital tract, pain is not enhanced by moving the cervix, and the adnexa are not tender to palpation. Purulent material may be expressed from the urethra or ducts of the Bartholin gland. Rectal gonorrhea, although often asymptomatic, may cause proctitis with symptoms of anal discharge, pruritus, bleeding, pain, tenesmus, and constipation. Asymptomatic rectal gonorrhea may not be due to anal intercourse but may represent colonization from vaginal infection.

Gonococcal ophthalmitis may be unilateral or bilateral. It may occur in any age group after inoculation of the eye with infected secretions. Ophthalmia neonatorum due to *N. gonorrhoeae* usually appears from 1–4 days after birth (Chapter 633). Ocular infection in older patients results from inoculation or autoinoculation from a genital site. The infection begins with mild inflammation and a serosanguineous discharge. Within 24?hr, the discharge becomes thick and purulent, and tense edema of the eyelids with marked chemosis occurs. If the disease is not treated promptly, corneal ulceration, rupture, and blindness may follow.

DISSEMINATED GONOCOCCAL INFECTION.

Hematogenous dissemination occurs in 1–3% of all gonococcal infections, more frequently after asymptomatic primary infections than symptomatic infections. Women account for the majority of cases, with symptoms beginning 7–30 days after infection and within 7 days of menstruation. The most common manifestations are asymmetric arthralgia, petechial or pustular acral skin lesions, tenosynovitis, suppurative arthritis, and, rarely, carditis, meningitis, and osteomyelitis. The most common initial symptoms are acute onset of polyarthralgia with fever. Only 25% of patients complain of skin lesions. Most deny genitourinary symptoms; however, primary mucosal infection is documented by genitourinary cultures. Approximately 80–90% of cervical cultures are positive in women with DGI. In males, urethral cultures are positive in 50–60%, pharyngeal cultures are positive in 10–20%, and rectal cultures are positive in 15% of cases.

DGI has been classified into two clinical syndromes that have some overlapping features. The first and more common is the **tenosynovitis-dermatitis syndrome**, which is characterized by fever, chills, skin lesions, and polyarthralgias predominantly involving the wrists, hands, and fingers. Blood culture results are positive in approximately 30–40% of cases, and synovial

fluid cultures are almost uniformly negative. The second syndrome is the **suppurative arthritis syndrome**, in which systemic symptoms and signs are less prominent and a monarticular arthritis, often involving the knee, is more common. A polyarthric phase may precede the monarticular infection. In cases of monarticular involvement, synovial fluid culture results are positive in approximately 45–55% and synovial fluid findings are consistent with septic arthritis. Blood culture results are usually negative. DGI in neonates usually occurs as a polyarticular septic arthritis.

Dermatologic lesions usually begin as painful, discrete, 1–20?mm pink or red macules that progress to maculopapular, vesicular, bullous, pustular, or petechial lesions. The typical necrotic pustule on an erythematous base is distributed unevenly over the extremities, including the palmar and plantar surfaces, usually sparing the face and scalp. The lesions number between 5 and 40; 20–30% may contain gonococci. Although immune complexes may be present in DGI, complement levels

are normal, and the role of the immune complexes in pathogenesis is uncertain.

Acute endocarditis is an uncommon (1–2%) but often fatal manifestation of DGI that usually leads to rapid destruction of the aortic valve. Acute pericarditis is a rarely described entity in patients with disseminated gonorrhea. Meningitis with *N. gonorrhoeae* has been documented. Signs and symptoms are similar to those of other causes of acute bacterial meningitis.

Diagnosis.

It is not possible to distinguish gonococcal from nongonococcal urethritis on the basis of symptoms and signs alone. Gonococcal urethritis and vulvovaginitis must be distinguished from other infections that produce a purulent discharge, including ß-hemolytic streptococci, *Chlamydia trachomatis, Mycoplasma hominis, Trichomonas vaginalis*, and *Candida albicans*. Rarely, infection with human herpesvirus type 2 may produce symptoms similar to those of gonorrhea.

In males with symptomatic urethritis, a presumptive diagnosis of gonorrhea can be made by identification of gram-negative intracellular diplococci (within leukocytes) in the urethral discharge. A similar finding in females is not sufficient because *Mima polymorpha* and *Moraxella*, which are normal vaginal flora, have a similar appearance. The sensitivity of the Gram stain for diagnosing gonococcal cervicitis and asymptomatic infections is also low. The presence of commensal *Neisseria* species in the oropharynx prevents the use of the Gram stain for diagnosis of pharyngeal gonorrhea. Nonpathogenic *Neisseria* are not intracellular.

Diagnosis of gonococcal disease depends on isolation of *N. gonorrhoeae*. Antibiotic susceptibility testing necessitates isolation by culture. Male urethral specimens are obtained by placing a small swab 2–3?cm into the urethra. Material for cervical cultures is obtained after wiping the exocervix and placing a swab in the cervical os and rotating it gently for several seconds. Rectal swabs are best obtained by passing a swab 2–4?cm into the anal canal; specimens that are heavily contaminated by feces should be discarded. For optimal culture results, specimens should be obtained with noncotton swabs (e.g., a urethrogenital Calgiswab), inoculated directly onto culture plates, and incubated immediately. The choice of anatomic sites to culture depends on the sites exposed and the clinical manifestations. Samples from the urethra should be cultured for heterosexual men, and samples from the endocervix and rectum should be cultured for all females, regardless of a history of anal intercourse. A pharyngeal culture should be obtained from both men and women if symptoms of pharyngitis are present or in the case of oral exposure to a person known to have genital gonorrhea. In a suspected case of child sexual abuse, rectal, pharyngeal, and urethral (males) or vaginal (females) swabs should be cultured. Culture of the endocervix should not be attempted until after puberty.

Specimens from sites (e.g., cervix, rectum, pharynx) that normally are colonized by other organisms should be inoculated on a selective culture medium, such as modified Thayer-Martin medium (fortified with vancomycin, colistin, nystatin, and trimethoprim to inhibit growth of indigenous flora). Specimens from sites that are normally sterile or minimally contaminated (i.e., synovial fluid, blood, cerebrospinal fluid) should be inoculated on a nonselective chocolate agar medium. If DGI is suspected, blood, pharynx, rectum, urethra, cervix, and synovial fluid (if involved) should be cultured. Cultured specimens should be incubated promptly at 35–37°C in 3–5% carbon dioxide. When specimens must be transported to a central laboratory for culture plating, a reduced, non-nutrient holding medium (i.e., Amies-modified Stuart medium) preserves specimens with minimal loss of viability for up to 6?hr. When transport may delay culture plating by more than 6?hr, it is preferable to inoculate the sample directly onto a culture medium and transport it at an ambient temperature in a candle jar. The Transgrow and JEMBEC systems of modified Thayer-Martin medium are alternative transport systems.

When microbiology laboratory facilities are not readily available or when patients may be unavailable for follow-up, rapid diagnostic techniques may prove efficacious. Care must be taken in selecting and interpreting results because many rapid tests are less specific than cultures. Nonculture tests include enzyme immunoassay (polyclonal antigonococcal antibodies for detection of gonococcal antigen), enzyme-linked immunosorbent assay (monoclonal antibodies), DNA probes, and nucleic acid amplification tests (polymerase chain reaction or ligase chain reaction). These tests appear to be less reliable than culture in low-risk asymptomatic patients, for nongenital specimens, and for specimens obtained from children. Nucleic acid amplification tests and DNA probes may prove to be comparable to culture in sensitivity and specificity. Nonculture tests cannot replace bacteriologic cultures for definitive diagnosis of *N. gonorrhoeae* or for antimicrobial susceptibility testing and may be more expensive. They may serve as useful adjuvant diagnostic tools in high-prevalence, transient populations (e.g., in adolescent STD clinics), in which a rapid and accurate presumptive diagnosis is required for prompt institution of therapy.

Gonococcal arthritis must be distinguished from other forms of septic arthritis as well as from rheumatic fever, rheumatoid arthritis, inflammatory bowel disease, and arthritis secondary to rubella or rubella immunization. Gonococcal conjunctivitis in the newborn period must be differentiated from chemical conjunctivitis caused by silver nitrate drops as well as from conjunctivitis caused by *C. trachomatis, Staphylococcus aureus*, group A or B streptococcus, *Pseudomonas aeruginosa, Streptococcus pneumoniae*, or human herpesvirus type 2.

Treatment.

All patients who are presumed or proven to have gonorrhea should be evaluated for concurrent syphilis, hepatitis B, human immunodeficiency virus, and *C. trachomatis* infection. The incidence of *Chlamydia* co-infection is 15–25% among males and 35–50% among females. Patients beyond the neonatal period should be treated presumptively for *C. trachomatis* infection (Chapter 208.2). Sexual partners exposed in the preceding 60 days should be examined, cultures should be obtained, and presumptive treatment started.

Because of the prevalence of penicillin-resistant *N. gonorrhoeae*, a third-generation cephalosporin, specifically ceftriaxone, is recommended as initial therapy for all ages. Antimicrobial resistance in *N. gonorrhoeae* occurs as plasmid-mediated resistance to penicillin and tetracycline, and chromosomally mediated resistance to penicillins, tetracyclines, spectinomycin, and recently to quinolones.

INFANT AND PEDIATRIC INFECTIONS.

Uncomplicated gonococcal infections in children should be treated with ceftriaxone (50?mg/kg in a single dose IM; maximum: 125?mg).

Children who cannot tolerate ceftriaxone may be treated with spectinomycin (40?mg/kg as a single injection IM; maximum: 2?g). Children who have bacteremia or arthritis should be treated with ceftriaxone (50?mg/kg/24?hr; maximum 1?g/day) for a minimum of 7 days if <45?kg and for a minimum of 10–14 days if =45?kg. Meningitis should be treated for 10–14 days, and endocarditis for a minimum of 28 days with ceftriaxone (50?mg/kg/dose q 12?hr; maximum: 1–2?g/dose). Neonatal gonococcal ophthalmia is treated effectively with ceftriaxone (50?mg/kg in a single dose IM; maximum: 125?mg); cefotaxime (100?mg/kg in a single dose IM) is an acceptable alternative. The conjunctivae should be irrigated frequently with physiologic saline solution. Infants born to mothers who have gonococcal infection at birth should also receive a single dose of ceftriaxone (50?mg/kg in a single dose IM; maximum: 125?mg). Neonatal sepsis should be treated parenterally for a minimum of 7 days and meningitis for a minimum of 10 days. Cefotaxime is recommended for infants with hyperbilirubinemia. Neonates with gonococcal ophthalmitis must be hospitalized and evaluated for DGI.

ADOLESCENT AND ADULT INFECTIONS.

A single dose of ceftriaxone (125?mg IM) eradicates pharyngeal and uncomplicated urogenital gonococcal infections. Ceftriaxone is safe and effective in pregnant women, and it probably aborts incubating syphilis. Alternative regimens include cefixime (400?mg PO), ciprofloxacin (500?mg PO), or ofloxacin (400?mg PO) in a single dose. The efficacy of cefixime against incubating syphilis is uncertain. Ciprofloxacin and ofloxacin should be avoided in pregnant women and are not approved for persons =18 yr of age in the United States. These drugs will not abort incubating syphilis. Spectinomycin (40?mg/kg as a single dose IM; maximum: 2?g) remains highly effective for genital and rectal gonorrhea in the United States, but is ineffective for pharyngeal infection and does not inhibit *T. pallidum*. Regardless of the regimen chosen, treatment should be followed by a regimen active against *C. trachomatis*. The recommended regimens are doxycycline (100?mg bid PO for 7 days) or azithromycin (1.0?g in a single dose PO). Most experts recommend a 7–10 day course of erythromycin in pregnant women. Adolescents and adults who are asymptomatic after treatment need not be cultured for a test of cure.

Hospitalization and parenteral administration of ceftriaxone (1?g/24?hr IV) are recommended for initial therapy of DGI. Patients should be examined for clinical evidence of endocarditis and meningitis. Alternatives for adults and older adolescents include intravenous cefotaxime (1?g q 8?hr IV) or ceftizoxime (1?g q 8?hr) or, for patients allergic to ß-lactam drugs, ciprofloxacin (500?mg q 12?hr IV), ofloxacin (400?mg q 12?hr IV), or spectinomycin (2?g q 12?hr IM). Treatment may be switched to oral regimens after 24–48?hr when clinical improvement is obvious. Oral regimens include cefixime (400?mg bid PO), ciprofloxacin (500?mg bid PO), or ofloxacin (400?mg bid PO) to complete 7 days of therapy. Gonococcal conjunctivitis should be treated with ceftriaxone (1?g IM in a single dose) with lavage of the infected eye with saline. Meningitis is treated with ceftriaxone (1–2?g q 12?hr IV) for 10–14 days. Endocarditis is treated with ceftriaxone (1–2?g q 12?hr IV) for at least 4 wk. Concurrent therapy for treatment of genital *Chlamydia* infection is important.

PELVIC INFLAMMATORY DISEASE.

PID encompasses a spectrum of infectious diseases of the upper genital tract due to *N. gonorrhoeae, C. trachomatis*, and endogenous flora (streptococci, anaerobes, gram-negative bacilli). Therapy must cover a broad spectrum and must be given to adolescents as inpatients. A commonly recommended therapeutic regimen is cefoxitin (2?g q 6?hr IV) or cefotetan (2?g q 12?hr IV), plus doxycycline (100?mg bid PO or q 12?hr IV). Therapy is continued for at least 48?hr after a patient shows improvement. Thereafter, oral doxycycline is given for a total of 10–14 days. An alternative recommended regimen is clindamycin (900?mg q 8?hr IV) plus a loading dose of gentamicin (2?mg/kg IV) followed by maintenance gentamicin (1.5?mg/kg q 8?hr IV). Therapy is then continued for 48?hr after improvement and is followed by oral clindamycin (450?mg qid PO) or oral doxycycline (100?mg bid PO) to complete 10–14 days of therapy. If an intrauterine device is present, it must be removed and an alternative form of birth control used. Sexual partners should be examined and treated for uncomplicated gonorrhea. Follow-up culture (test of cure) of cephalosporin-doxycycline therapy of gonococcal STD is not recommended owing to the low treatment failure rate. A follow-up examination and culture are recommended in 1–2 mo to evaluate the possibility of reinfection or, rarely, treatment failure.

Complications.

Complications of gonorrhea result from the spread of gonococci from a local site of invasion. The interval between primary infection and development of a complication is usually days to weeks. In postpubertal females, endometritis may occur, especially during menses. This may progress to salpingitis and peritonitis (PID). Manifestations of PID include signs of lower genital tract infection (e.g., vaginal discharge, suprapubic pain, cervical tenderness) and upper genital tract infection (e.g., fever, leukocytosis, elevated erythrocyte sedimentation rate, and adnexal tenderness or mass). The differential diagnosis includes gynecologic (ovarian cyst, ovarian tumor, ectopic pregnancy) and intra-abdominal (appendicitis, urinary tract infection, inflammatory bowel disease) pathology.

Once inside the peritoneum, gonococci may seed the liver capsule, causing a perihepatitis. The resultant right upper quadrant pain, with or without signs of salpingitis, is known as the Fitz-Hugh-Curtis syndrome. Perihepatitis may also be caused by *C. trachomatis*. Progression to PID occurs in about 20% of cases of gonococcal cervicitis. *N. gonorrhoeae* is isolated in approximately 40% of cases of PID in the United States. Untreated cases may lead to hydrosalpinx, pyosalpinx, tubo-ovarian abscess, and eventual sterility. Even with adequate treatment of PID, the risk of sterility caused by bilateral tubal occlusion approaches 20% after one episode of salpingitis and exceeds 60% with three or more episodes. The risk of ectopic pregnancy is increased approximately sevenfold after one or more episodes of salpingitis. Additional sequelae of PID include chronic pain, dyspareunia, and increased risk of recurrent PID.

Urogenital gonococcal infection acquired during the first trimester of pregnancy

carries a high risk of septic abortion. After 16 wk, infection causes chorioamnionitis, a major cause of premature rupture of the membranes and premature delivery.

Prognosis.

Prompt diagnosis and correct therapy ensure complete recovery from uncomplicated gonococcal disease. Complications and permanent sequelae may be associated with delayed treatment, recurrent infection, metastatic sites of infection (meninges, aortic valve), and delayed or topical therapy of gonococcal ophthalmia.

Prevention.

Efforts to develop a gonococcal pilus vaccine have been unsuccessful thus far. The high degree of interstrain and intrastrain antigenic variability of pili poses a formidable deterrent to the development of a single effective pilus vaccine. Other gonococcal surface structures such as the porin protein, stress proteins, and lipo-oligosaccharides may prove more promising as vaccine candidates. In the absence of a vaccine, prevention of gonorrhea can be achieved through education, use of barrier contraceptives (especially condoms), intensive epidemiologic and bacteriologic surveillance (screening sexual contacts), and early identification and treatment of infected contacts.

Gonococcal ophthalmia neonatorum can be prevented by instilling 2 drops of a 1% solution of silver nitrate into each conjunctival sac shortly after birth (Chapter 617). Erythromycin (0.5%) or tetracycline (1%) ophthalmic ointment may also be used.

Chapter 178 - *Haemophilus influenzae*

Robert S. Daum

Approximately 100 yr after the recognition of *Haemophilus influenzae* as the cause of several important syndromes in childhood, an effective vaccine to prevent these illnesses was introduced in the United States, resulting in a dramatic decrease in the prevalence of infections due to this organism. However, mortality and morbidity from *H. influenzae* type b infection remain a problem worldwide, primarily in unimmunized populations.

Etiology.

H. influenzae is a fastidious, gram-negative, pleomorphic coccobacillus that requires **factor X (hematin)** and **factor V (phosphopyridine nucleotide)** for growth.

Some *H. influenzae* isolates are surrounded by a polysaccharide capsule. Such isolates can be serotyped into six antigenically and biochemically distinct types, designated a–f. The most virulent isolates belong to serotype b.

Epidemiology.

Before the advent of effective conjugate vaccine use in 1988, *H. influenzae* was a major cause of certain invasive diseases in children. Serotype b organisms accounted for >95% of these cases. There was a striking age distribution of cases; >90% occurred in children <5 yr of age, and the majority occurred in children <2 yr of age. The annual attack rate of invasive disease was estimated to be 64–129 cases/100,000 children <5 yr of age per year. Invasive disease caused by other capsular serotypes is much less frequent; the incidence of invasive disease has been estimated at about 0.7 cases/100,000 children <5 yr of age per year. The recent descriptions of small clusters of serotype a and f infections may reflect low-level events and important trends for the future. Nonencapsulated (nontypable) *H. influenzae* organisms cause invasive disease in neonates, immunocompromised children, and children in certain developing countries. Nontypable isolates are common etiologic agents in otitis media, in sinusitis, and in chronic bronchitis in adults.

Humans are the only natural hosts for *H. influenzae*. This species is a constituent of the normal respiratory flora in 60–90% of healthy children. Most isolates are nontypable. Colonization by serotype b organisms is infrequent. Before the advent of conjugate vaccine immunization, *H. influenzae* type b could be isolated from the pharynx of 2–5% of healthy preschool and school-aged children; lower rates occurred among infants and adults. Such asymptomatic colonization with *H. influenzae* type b probably occurs at lower rates in immunized populations, although, importantly, the bacterium continues to circulate.

The incidence of *H. influenzae* type b disease has declined by >99% in the vaccine era. From 1989–1997, the incidence of invasive *H. influenzae* type b disease among children <5 yr of age declined 99%, from 34 to 0.4 cases/100,000 children/yr. Because a similar decline in invasive *H. influenzae* disease due to other serotypes or due to nontypable organisms has not occurred, the proportion of cases due to serotype b organisms has also declined and accounted for only 32–41% of reported cases in 1996–1997. Meeting the Centers for Disease Control and Prevention (CDC) objective of eliminating invasive *H. influenzae* type b disease by 2010 will require improved vaccine coverage, standardization of serotyping techniques, complete case ascertainment, and serotype reporting for all cases. The continued circulation of the serotype b organism despite current vaccine coverage levels suggests that meeting this objective may be a formidable task. Also, continued effort will be required to provide currently available conjugate vaccines to children in developing countries where affordability remains an important issue.

The few cases of serotype b invasive disease now occur in both unvaccinated and fully vaccinated children; about half occur in infants <6 mo, too young to have received a three-dose primary series. Among those cases that are age-eligible to have received such a series, about one third had received at least a three-dose primary series, and about one half of these had also received a booster dose.

Certain groups and individuals have been identified to have an increased incidence of invasive disease, including Alaskan Eskimos, Apaches, Navajos, and blacks. In these populations, the proportion of cases of invasive disease in children <12 mo has been relatively high. Persons known to be at an increased risk for invasive disease have also included those with sickle cell disease, asplenia, congenital and acquired immunodeficiencies, and malignancies. Nonvaccinated infants who had previously documented invasive infection are at increased risk for recurrence.

Socioeconomic risk factors for invasive *H. influenzae* type b disease include childcare outside the home, the presence of siblings of elementary school age or younger, short duration of breast-feeding, and parental smoking. Previous hospitalization for invasive *H. influenzae* type b disease and a history of otitis media are associated with an increased risk for invasive disease. Much less is known about the epidemiology of *H. influenzae* infections other than for serotype b.

Among age-susceptible household contacts who have been exposed to a case of invasive *H. influenzae* type b disease, there is increased risk of secondary cases of invasive disease in the first 30 days, especially in susceptible children <24 mo of age.

The mode of transmission is most commonly by direct contact or inhalation of respiratory tract droplets containing *H. influenzae*. The incubation period for invasive disease is variable, and the exact period of communicability is unknown. Most

children with invasive *H. influenzae* type b disease are colonized in the nasopharynx before initiation of antimicrobial therapy; 25–40% may remain colonized during the first 24?hr of therapy.

Pathogenesis.

The precise mechanisms that facilitate successful colonization of the respiratory epithelium have not been identified. Following bacterial attachment to the respiratory mucosa, the events that result in entry into the intravascular compartment by serotype b organisms are unclear. Once there, however, type b strains resist intravascular clearance mechanisms more readily than do strains of other serotypes and nonencapsulated organisms. Whether it is the type b PRP capsule itself that confers the potential for invasive disease or another closely linked virulence factor is not certain. Once established, the magnitude of *H. influenzae* type b bacteremia and its duration determine the likelihood of dissemination of bacteria into sites such as the meninges or joints.

Noninvasive *H. influenzae* infections such as otitis media, sinusitis, and bronchitis, usually caused by nontypable strains, probably gain access to sites such as the middle ear and sinus cavities by direct extension from the pharynx. The factors facilitating spread from the pharynx include eustachian tube dysfunction and antecedent viral infections of the upper respiratory tract.

ANTIBIOTIC RESISTANCE.

Most *H. influenzae* isolates are susceptible to ampicillin or amoxicillin but about one third produce a ß-lactamase and are therefore resistant. Rarely, a ß-lactamase-negative isolate may be ampicillin-resistant by a different resistance mechanism.

Chloramphenicol is effective against most isolates of *H. influenzae* regardless of ß-lactamase production. The disadvantages of chloramphenicol include the need for complex monitoring strategies and the rare occurrence of idiosyncratic aplastic anemia. Isolates of *H. influenzae* type b have been identified as resistant to chloramphenicol, but such resistance has remained relatively rare (about 0.2% of isolates) in the United States and throughout the world, although higher rates have been reported in a few locales. Isolates resistant to both chloramphenicol and ampicillin have been identified rarely (<1% of isolates). Resistance to trimethoprim-sulfamethoxazole (TMP-SMZ) has been infrequent (<10%).

Until recently, amoxicillin-clavulanate was considered uniformly active against *H. influenzae* clinical isolates. However, about 3% of ß-lactamase–positive isolates are resistant to amoxicillin-clavulanate. Furthermore, amoxicillin-clavulanate offers no apparent synergy against ampicillin-resistant isolates that do not elaborate ß-lactamase. Among the newer macrolides, 99% and 78% of *H. influenzae* isolates were susceptible to azithromycin and clarithromycin, respectively, whereas the activity of erythromycin against *H. influenzae* clinical isolates has been considered to be poor. Resistance to quinolones is believed to be infrequent. Resistance to extended-spectrum cephalosporins, which are commonly used in therapy, has not been documented.

IMMUNITY.

The most important element of host defense is antibody directed against the type b capsular polysaccharide, PRP. In the prevaccination era, anti-PRP antibody was acquired in an age-related fashion; its mechanism of action is to facilitate clearance of *H. influenzae* type b from blood. This is related in part to its opsonic activity; other antibodies directed against antigens such as outer membrane proteins or lipopolysaccharides may also have a role in opsonization. Both the classic and alternative complement pathways are important in the opsonization of *H. influenzae* type b. The macrophages of the reticuloendothelial system aid in intravascular clearance of *H. influenzae* type b by affecting intracellular killing after opsonization.

Before the introduction of vaccination and among recipients of unconjugated PRP vaccines, protection from *H. influenzae* type b infection was presumed to correlate with the concentration of circulating anti-PRP antibody at the time of exposure. A serum antibody concentration of 0.15–1.0?µg/mL was considered protective against invasive infection; the higher concentration in vaccines may predict maintenance of a level of >0.15?µg/mL over time. Most infants lack an anti-PRP antibody concentration of this magnitude and are susceptible to disease on encounter with *H. influenzae* type b. This lack of antibody in young infants may reflect a maturational delay in the immunologic response to thymus-independent type 2 (TI-2) antigens such as unconjugated PRP, and it was thought to explain the high incidence of serotype b infections in young infants in the prevaccination era.

Unlike the PRP unconjugated vaccine, the conjugate vaccines—with the exception of PRP-OMP, which also has thymus-independent type 1 (TI-1) properties—act as thymus-dependent (TD) antigens (Table 178–1). They elicit serum antibody responses in young infants, although repeat doses may be required, and prime memory antibody responses on subsequent encounters

TABLE 178-1 -- ***Haemophilus influenzae*** **Type b Conjugate Vaccines**

Abbreviation	Trade Name	Manufacturer	Protein Carrier
HbOC	HibTITER	Wyeth	CRM_{197} (a nontoxic utant of diphtheria toxin)
PRP-OMP[*]	PedvaxHIB	Merck	OMP (an outer embrane protein complex of *Neisseria meningitidis*)

PRP-T‡	ActHIB	Aventis Pasteur	Tetanus toxoid	
		OmniHIB	Aventis Pasteur‡	Tetanus toxoid

PRP-OMP is also available as a combination vaccine with hepatitis B vaccine (Comvax).This should not be used for hepatitis B immunization at birth.
†PRP-T can be reconstituted with Connaught DTaP vaccine (Tripedia), to produce a combination marketed asTriHIBit, which is acceptable only for the booster (4th) dose in infants = 15 mo of age.
‡Marketed by GlaxoSmithKline in the United States.

with PRP. The concentration of circulating anti-PRP antibody in a child primed by a conjugate vaccine may not correlate precisely with protection, because a memory response may occur rapidly on exposure to PRP and provide protection.

Less is known about immunity to nontypable *H. influenzae*. Evidence suggests that antibodies directed against one or more outer membrane proteins (OMPs) are bactericidal and protect against experimental challenge. In infant rats, antibody to P6, a major OMP, is bactericidal for encapsulated and nontypable *H. influenzae* and is protective against *H. influenzae* type b disease. Another OMP, P2, has substantial interstrain heterogeneity. Antibody elicited to the nonconserved regions of P2 had complement-dependent bactericidal activity to the homologous strain. Monoclonal antibodies directed against a group of surface-exposed high molecular weight OMPs have provided protection in experimental infection in animals.

Diagnosis.

Presumptive identification of *H. influenzae* is established by direct examination of the collected specimen after Gram staining. Because of its small size, pleomorphism, poor uptake of stain by some isolates, and the tendency for fluids, particularly when proteinaceous, to have a red background, *H. influenzae* is sometimes difficult to visualize. Because identification of microorganisms on smear by either technique requires at least 10^5 bacteria/mL, failure to visualize them does not preclude their presence.

Culture of *H. influenzae* requires prompt transport and processing of specimens because the organism is fastidious. Specimens should not be exposed to drying or temperature extremes. Primary isolation of *H. influenzae* can be accomplished on chocolate agar, *Haemophilus* isolation agar, or on blood agar plates using the *Staphylococcus* streak technique.

Serotyping of *H. influenzae* is accomplished by slide agglutination with type-specific antisera. Accurate serotyping is essential to monitor progress toward elimination of serotype b invasive disease. Timely reporting of cases to public health authorities should be ensured.

Clinical Manifestations and Treatment.

The clinical manifestations and treatment of all invasive *H. influenzae* disease are similar regardless of serotype. The initial antibiotic therapy of invasive infections possibly due to *H. influenzae* type b should be a parenterally administered antimicrobial agent effective in sterilizing all foci of infection and effective against ampicillin-resistant strains. Extended-spectrum cephalosporins, such as cefotaxime or ceftriaxone, have been used as the initial antimicrobial agent when *H. influenzae* type b is considered a likely pathogen, and they have achieved popularity because of their relative lack of serious adverse effects and ease of administration. Alternatively, chloramphenicol can be used with ampicillin. After the antimicrobial susceptibility of the isolate has been determined, an appropriate agent can be selected to complete the therapy.

Ampicillin remains the drug of choice for the therapy of infections caused by susceptible isolates. If the isolate is resistant to ampicillin, extended-spectrum cephalosporins such as cefotaxime or ceftriaxone are useful; the latter can be administered once daily in selected circumstances for outpatient therapy. Chloramphenicol also has extensive clinical experience.

Oral antimicrobial agents are sometimes used to complete a course of therapy initiated by the parenteral route. If the organism is susceptible to ampicillin, amoxicillin is the drug of choice. An oral third-generation cephalosporin (e.g., cefixime, cefpodoxime) or amoxicillin-clavulanate may be used when the isolate is resistant to ampicillin. Chloramphenicol is another option that continues to enjoy popularity in some countries because of its low cost.

MENINGITIS.

Clinically, meningitis due to *H. influenzae* type b cannot be differentiated from that due to *Neisseria meningitidis* or *Streptococcus pneumoniae* and may be complicated by other foci of infection, such as the lungs, joints, bones, or pericardium (Chapter 594.1).

Antimicrobial therapy should be administered parenterally for 7–14 days for uncomplicated cases. Cefotaxime, ceftriaxone, ampicillin, and chloramphenicol all are thought to cross the blood-brain barrier during acute inflammation in concentrations adequate to render them effective for *H. influenzae* meningitis. Chloramphenicol has been administered orally to complete a therapeutic regimen for meningitis.

The prognosis of *H. influenzae* type b meningitis depends on the age at presentation, the duration of illness before appropriate antimicrobial therapy, the CSF capsular polysaccharide concentration, and the rapidity with which it is cleared from CSF, blood, and urine. Low intelligence quotients correlate with clinically manifested inappropriate secretion of antidiuretic hormone and evidence of focal neurologic deficits at presentation. About 6% of patients with *H. influenzae* type b meningitis are left with some hearing impairment, probably because of inflammation of the cochlea and the labyrinth. Dexamethasone (0.6?mg/kg/24?hr divided q 6?hr for 2 days), particularly when given shortly before or concurrent with the initiation of antimicrobial therapy, decreases the incidence of hearing loss. Major neurologic

sequelae of *H. influenzae* type b meningitis include behavior problems, language disorders, delayed development of language, impaired vision, mental retardation, motor abnormalities, ataxia, seizures, and hydrocephalus.

CELLULITIS.

Children with *H. influenzae* cellulitis often have an antecedent upper respiratory tract infection. They usually have no prior history of trauma, and the infection is thought to represent seeding of the organism to the involved soft tissues during bacteremia. The head and neck, particularly the cheek and preseptal region, are the most common sites of involvement. The involved region generally has indistinct margins and is tender and indurated. Buccal cellulitis is classically erythematous with a violaceous hue, although this sign may be absent. *H. influenzae* may often be recovered directly from an aspirate. The blood culture may reveal the causative organism. Other foci of infection may be present concomitantly, particularly in children <18 mo of age or with fever. A diagnostic lumbar puncture should be considered at the time of diagnosis for these children.

Parenteral antimicrobial therapy is indicated until patients become afebrile, after which an appropriate orally administered antimicrobial agent may be substituted. A 7–10 day course is customary.

PRESEPTAL CELLULITIS.

Infection involving the superficial tissue layers anterior to the orbital septum is termed preseptal cellulitis, which may be caused by *H. influenzae*. Uncomplicated preseptal cellulitis does not imply a risk for visual impairment or direct central nervous system extension. However, concurrent bacteremia may be associated with the development of meningitis. *H. influenzae* preseptal cellulitis is characterized by fever, edema, tenderness, warmth of the lid, and, occasionally, purple discoloration. Evidence of interruption of the integument is usually absent. Conjunctival drainage may be associated. *S. pneumoniae, Staphylococcus aureus*, and group A streptococcus cause clinically indistinguishable preseptal cellulitis. The latter two pathogens are more likely when fever is absent and with an interruption of the integument (e.g., an insect bite).

Those with preseptal cellulitis in whom *H. influenzae* or *S. pneumoniae* are etiologic considerations (i.e., young age, high fever, intact integument) should have blood submitted for culture, and a diagnostic lumbar puncture should be considered.

Parenteral antibiotics are indicated for preseptal cellulitis. Because *S. aureus, S. pneumoniae*, and group A ß-hemolytic streptococci are other causes, empirical therapy should include agents active against these pathogens. Patients with preseptal cellulitis without concurrent meningitis should receive parenteral therapy for about 5 days until fever and erythema have abated. In uncomplicated cases, antimicrobial therapy should be given for a total of 10 days.

ORBITAL CELLULITIS.

Infections of the orbit are infrequent and usually complicate acute ethmoid and sphenoid sinusitis. Orbital cellulitis may present with lid edema but is distinguished by the presence of proptosis, chemosis, impaired vision, limitation of the extraocular movements, decreased mobility of the globe, or pain on movement of the globe. The distinction between preseptal and orbital cellulitis may be difficult. The extent of the infection is best delineated by CT.

Orbital infections are treated with parenteral therapy for at least 14 days. Underlying sinusitis or orbital abscess may require surgical drainage and more prolonged antimicrobial therapy.

SUPRAGLOTTITIS OR ACUTE EPIGLOTTITIS.

Epiglottitis is a cellulitis of the tissues comprising the laryngeal inlet (Chapter 371). It has become exceedingly rare. Direct invasion of the involved tissues by *H. influenzae* type b is probably the initiating pathophysiologic event. This dramatic, potentially lethal condition usually occurs in children 2–7 yr of age. Because of the risk of sudden, unpredictable airway obstruction, supraglottitis is a medical emergency. Pneumonia is detected by chest radiograph in about 25% of cases. Other foci of infection, such as meningitis, are rare. Antimicrobial therapy directed against *H. influenzae* type b should be administered parenterally but only after the airway is secured, and therapy should be continued until patients are able to take fluids by mouth. The duration of antimicrobial therapy typically is 7 days.

PNEUMONIA.

The true incidence of *H. influenzae* type b pneumonia in children is unknown because invasive procedures are required to obtain cultures and are seldom performed (Chapter 389). The signs and symptoms of pneumonia due to *H. influenzae* cannot be differentiated from those of pneumonia caused by many other microorganisms. Other foci of infection may be present concomitantly.

Children suspected of having *H. influenzae* type b pneumonia who are <12 mo should receive parenteral antimicrobial therapy initially because of their increased risk for bacteremia and its complications. Older children who do not appear severely ill may be managed with an orally administered antimicrobial. Therapy is continued for 7–10 days of combined parenteral-oral therapy.

Uncomplicated pleural effusion associated with *H. influenzae* pneumonia requires no special intervention. However, if empyema develops, insertion of a chest tube and a more prolonged course of antimicrobial therapy may be necessary.

SUPPURATIVE ARTHRITIS.

Large joints, such as the knee, hip, ankle, and elbow, are affected most commonly (Chapter 674). Other foci of infection may be present concomitantly. Although single joint involvement is the rule, multiple joint involvement occurs in about 6% of cases. The signs and symptoms of septic arthritis due to *H. influenzae* are indistinguishable from those of arthritis caused by other bacteria.

Uncomplicated septic arthritis should be treated with an appropriate antimicrobial administered parenterally for at least 5–7 days. If the clinical response is satisfactory the remainder of the course of antimicrobial treatment may be given orally. Therapy is typically given for 3 wk for uncomplicated septic arthritis, but it may be continued beyond 3 wk until the C-reactive protein is normal.

PERICARDITIS.

H. influenzae is a rare cause of bacterial pericarditis (Chapter 432). Affected children often have had an antecedent upper respiratory tract infection. Fever, respiratory distress, and tachycardia are consistent findings. Other foci of infection may be present concomitantly.

The diagnosis may be established by recovery of the organism from blood or pericardial fluid. Gram stain or detection of PRP in pericardial fluid, blood, or urine (when serotype b organisms are the cause) may aid the diagnosis. Antimicrobials should be provided parenterally in a regimen similar to that used for meningitis (Chapter 594.1). Pericardiectomy is useful for draining the purulent material effectively and preventing tamponade and constrictive pericarditis.

BACTEREMIA WITHOUT AN ASSOCIATED FOCUS.

Bacteremia due to *H. influenzae* type b may be associated with fever without any apparent focus of infection (Chapter 162). In this situation, risk factors for “occult” bacteremia include the magnitude of fever (=39°C) and the presence of leukocytosis (=15,000 cells/µL). About 25% of children with occult *H. influenzae* type b bacteremia develop meningitis if left untreated. In the vaccine era, this *H. influenzae* type b infection has become exceedingly rare. When it does occur, however, the child should be re-evaluated for a focus of infection and a second blood culture obtained. In general, the child should be hospitalized and given parenteral antimicrobial therapy after a diagnostic lumbar puncture and chest radiograph are obtained.

MISCELLANEOUS INFECTIONS.

Urinary tract infection, epididymo-orchitis, cervical adenitis, acute glossitis, infected thyroglossal duct cysts, uvulitis, endocarditis, endophthalmitis, primary peritonitis, osteomyelitis and periappendiceal abscess are rarely caused by *H. influenzae*.

INVASIVE DISEASE IN NEONATES.

In neonates with invasive *H. influenzae* infection, nontypable isolates are more common than serotype b isolates, although both are rare. When illness occurs in the first 24?hr of life, especially in association with maternal chorioamnionitis or prolonged rupture of membranes, transmission of the organism to the infant is likely to have occurred through the maternal genital tract, which may be (<1%) colonized with nontypable *H. influenzae*. Manifestations of neonatal invasive infection include bacteremia with sepsis, pneumonia, respiratory distress syndrome with shock, conjunctivitis, scalp abscess or cellulitis, or meningitis. Less commonly, mastoiditis, septic arthritis, or a congenital vesicular eruption may occur.

OTITIS MEDIA.

Acute otitis media is one of the most common infectious diseases of childhood (Chapter 630). It is thought to result from the spread of bacteria from the nasopharynx through the eustachian tube into the middle-ear cavity. Usually because of a preceding viral upper respiratory tract infection, the mucosa in the area becomes hyperemic and swollen, resulting in obstruction and an opportunity for bacterial multiplication in the middle ear.

The most common bacterial pathogens are *S. pneumoniae, H. influenzae*, and *Moraxella catarrhalis*. Most *H. influenzae* isolates are nontypable. Amoxicillin (80–90?mg/kg/24?hr) is a suitable first-line oral antimicrobial agent; the combined probability of the causative isolate being resistant to amoxicillin and of invasive potential is sufficiently low to continue to justify this approach. Alternatively, a single dose of ceftriaxone may constitute adequate therapy.

In the case of treatment failure or if a ß-lactamase–producing isolate is obtained by tympanocentesis or from drainage fluid, amoxicillin-clavulanate, erythromycin-sulfisoxazole, and cefaclor are among the available alternatives. The latter combination may be useful as first-line agents for patients allergic to ß-lactam compounds.

CONJUNCTIVITIS.

Acute infection of the conjunctiva is the most common eye infection in childhood (Chapter 617). In neonates, *H. influenzae* is an infrequent cause. However, it is an important pathogen in older children, as are *S. pneumoniae* and *S. aureus*. Most *H. influenzae* isolates associated with conjunctivitis are nontypable, although serotype b isolates and other microorganisms are occasionally found. Empirical treatment of conjunctivitis beyond the neonatal period usually consists of topical antimicrobial therapy with sulfacetamide and erythromycin.

SINUSITIS.

H. influenzae is an important cause of acute sinusitis in children, second in frequency only to *S. pneumoniae* (Chapter 365). Chronic sinusitis lasting >1 yr or severe sinusitis requiring hospitalization is often caused by *S. aureus* or anaerobes such as *Peptococcus, Peptostreptococcus*, or *Bacteroides* species. Nontypable *H. influenzae* and viridans group streptococci are also frequently recovered.

For uncomplicated sinusitis, amoxicillin is acceptable initial therapy. However, if clinical improvement does not occur, a broader-spectrum regimen may be appropriate, such as amoxicillin-clavulanate; hospitalization with parenteral therapy is occasionally required. For uncomplicated sinusitis, a 10-day course is sufficient.

Prevention.

Universal immunization with *H. influenzae* type b conjugate vaccine is recommended for all infants. Chemoprophylaxis is indicated if close contacts are unvaccinated.

CHEMOPROPHYLAXIS.

Unvaccinated children <48 mo of age in close contact are at increased risk of invasive infection when exposed to an index case with invasive *H. influenzae* type b infection. The risk of secondary disease is inversely related to age (for children >3 mo of age). About half of the cases of secondary disease among susceptible household contacts occur in the 1st wk after hospitalization of the index patient. Because many children are now protected against *H. influenzae* type b by prior immunization, the need for chemoprophylaxis has greatly decreased.

The goal of chemoprophylaxis is to prevent a susceptible child from acquiring *H. influenzae* type b from contacts by eliminating colonization in the close contacts. Rifampin prophylaxis is indicated for all members of the close contact group, including the index patient, if one or more children <48 mo is not fully immunized.

Parents of children hospitalized for invasive *H. influenzae* type b disease should be told that there is an increased risk for secondary infection due to this organism in other young children in the same household if they are partially immunized. Parents of children exposed to a single case of invasive *H. influenzae* type b disease in a child-care center or nursery school should be similarly informed, although there is disagreement about the use of rifampin for these children.

For chemoprophylaxis, children should be given rifampin orally (0–1 mo of age, 10?mg/kg/dose; >1 mo, 20?mg/kg/dose, not to exceed 600?mg/dose), once each a day for 4 consecutive days. The adult dose is 600?mg once daily. It is not recommended for pregnant women, because the effects on a fetus are not established. Because rifampin induces enzymes that metabolize oral contraceptives, other methods of contraception should be implemented during the period of rifampin administration. Rifampin turns body fluids (e.g., urine, saliva, tears) reddish orange and may permanently stain soft contact lenses.

VACCINE.

Three *H. influenzae* type b conjugate vaccines are available that differ in the carrier protein used, the saccharide molecular size, and the method of conjugating the saccharide to the protein (see Table 178–1 and Chapter 282). Combination vaccines consisting of a *H. influenzae* type b conjugate vaccine

and one or more other vaccines recommended for routine administration in childhood are under development. Currently available combinations are PRP-OMP combined with hepatitis B vaccine (Comvax) and a DtaP vaccine that can be combined with PRP-T for the fourth dose only. Many attempts to combine DTaP (acellular pertussis vaccine) with a *H. influenzae* type b conjugate vaccine have resulted in decreased anti-PRP antibody.

Chapter 179 - Chancroid (*Haemophilus ducreyi*)

Parvin Azimi

Chancroid is a sexually transmitted disease characterized by painful genital ulceration and inguinal lymphadenopathy that is caused by *Haemophilus ducreyi*, a fastidious gram-negative bacillus. Chancroid is prevalent in many countries and endemic in some areas of the United States; it is a risk factor for transmission of HIV. Diagnosis of chancroid in infants and children is strong evidence of sexual abuse.

Infection begins with a small inflammatory papule on the preputial orifice or frenulum in men and on the labia, fourchette, or perineal region in women. The lesion becomes pustular, eroded, and ulcerative within 2–3 days. Painful, tender inguinal lymphadenitis (bubo) occurs in >50% of cases. Unlike lymphogranuloma venereum (Chapter 208.4), the ulcer of chancroid is concurrent with lymphadenopathy.

Diagnosis is usually established by the clinical presentation and the exclusion of both *Treponema pallidum* and herpes simplex virus infections. Gram stain of ulcer secretions may show gram-negative coccobacilli in parallel clusters (school of fish). Culture requires special media and is 80% or less sensitive. Indirect immunofluorescence using monoclonal antibodies or polymerase chain reaction may become the best means for diagnosis.

Most *H. ducreyi* organisms are resistant to penicillin and ampicillin because of plasmid-mediated ß-lactamase production. Spread of plasmid-mediated resistance among *H. ducreyi* has resulted in lack of efficacy of previously useful drugs such as sulfonamides and tetracyclines as well. The recommended treatment of chancroid is azithromycin (1?g as a single dose PO) or ceftriaxone (250?mg as a single dose IM). Alternative regimens include ciprofloxacin (500?mg bid PO for 3 days, for persons =18 yr of age) or erythromycin (500?mg qid PO for 7 days). Fluctuant nodes may require drainage. Symptoms usually resolve within 3–7 days. Relapses can usually be treated successfully with the original treatment regimen. Patients with HIV infection may require longer duration of treatment.

Patients with chancroid should be evaluated for other sexually transmitted diseases; an estimated 10% of patients have concomitant syphilis or genital herpes. Sexual contacts of patients with chancroid should be evaluated and treated.

Chapter 180 - Pertussis (*Bordetella pertussis* and *B. parapertussis*)

Sarah S. Long

Pertussis is an acute respiratory tract infection that was well described in the 1500s. Current worldwide prevalence is diminished only by active immunization. Sydenham first used the term *pertussis* (intense cough) in 1670; it is preferable to **whooping cough** because most infected individuals do not "whoop."

Etiology.

Bordetella pertussis is the sole cause of epidemic pertussis and the usual cause of sporadic pertussis. *B. parapertussis* is an occasional cause of pertussis, accounting for fewer than 5% of isolates of *Bordetella* species in the United States. *B. parapertussis* contributes significantly to total cases of pertussis in other areas such as Scandinavia, the Czech Republic, Slovakia, and the Russian federation. *B. pertussis* and *B. parapertussis* are exclusive pathogens of humans (and some primates). *B. bronchiseptica* is a common animal pathogen; occasional case reports in humans involve any body site and typically occur in immunocompromised patients or young children with unusual exposure to animals. Protracted coughing can be caused by *Mycoplasma*, parainfluenza or influenza viruses, enteroviruses, respiratory syncytial virus, or adenoviruses. None is an important cause of pertussis.

Epidemiology.

Sixty million cases of pertussis a year occur worldwide, resulting in more than 500,000 deaths. During the prevaccine era of 1922–1948, pertussis was the leading cause of death due to communicable disease among children <14 yr of age in the United States. Widespread use of pertussis vaccine led to a greater than 99% decline in cases. The pivotal role of vaccine in disease control is reflected in the continued high incidence of pertussis in developing countries, and resurgence in other countries where vaccine coverage is low or where less potent vaccine may have been used. After the lowest number of cases in the United States reported in 1976, lax implementation of policy is partially responsible for the increase in annual pertussis incidence to 1.2 cases/100,000 population from 1980 through 1989 and epidemic pertussis in many states in 1989–1990, 1993, and 1996. The more than 7,500 cases reported to the Centers for Disease Control and Prevention in 1996 are the highest incidence since 1967. During the 1990s in the United States, rates of pertussis during interepidemic years have not returned to baseline, with between 6,000 to 8,000 cases reported annually since 1996. There is good evidence that the diagnosis of pertussis is underconsidered, underproven, and underreported.

Pertussis is endemic, with superimposed epidemic cycles every 3–4 yr after accumulation of a sizable susceptible cohort. The majority of cases occur from July through October. Pertussis is extremely contagious, with attack rates as high as 100% in susceptible individuals exposed to aerosol droplets at close range. *B. pertussis* does not survive for prolonged periods in the environment. Chronic carriage by humans is not documented. After intense exposure as in households, the rate of subclinical infection is as high as 80% in fully immunized and naturally immune individuals. When carefully sought, however, a symptomatic source case can be found for most patients.

Neither natural disease nor vaccination provides complete or lifelong immunity against reinfection or disease. Protection against typical disease begins to wane 3–5 yr after vaccination and is unmeasurable after 12 yr. Subclinical reinfection undoubtedly contributes significantly to immunity against disease ascribed to both vaccine and prior infection. Adults in the United States have inadequate antibody to *B. pertussis*. Despite history of disease or complete immunization, outbreaks of pertussis have occurred in the elderly, in nursing homes, in residential facilities with limited exposures, in highly immunized suburbia, and in adolescents and adults with lapsing time since immunization. Coughing adolescents and adults (usually not recognized as having pertussis) currently are the major reservoir for *B. pertussis* and are the usual sources for "index cases" in infants and children.

In the prevaccine era and in countries such as Germany, Sweden, and Italy where immunization was limited, the peak incidence of pertussis is in children 1–5 yr of age; infants account for <15% of cases. In contrast, in the United States in recent years, approximately one half of cases have occurred in infants younger than 1 yr of age and one fourth in adolescents and adults. Possible explanations for increases in disease incidence and differences in ages affected include decreased vaccine efficacy, waning immunity, increased awareness and diagnosis, and enhanced surveillance. Without natural reinfection with *B. pertussis* or repeated booster vaccinations, adolescents and adults are susceptible to clinical disease if exposed, and mothers provide little if any passive protection to young infants.

Pathogenesis.

Bordetella organisms are tiny gram-negative coccobacilli that grow aerobically on starch blood agar or completely synthetic media with nicotinamide growth factor, amino acids for energy, and charcoal or cyclodextrin resin to absorb noxious substances. *Bordetella* species share a high degree of DNA homology among virulence genes. Only *B. pertussis* expresses **pertussis toxin** (PT), the major virulence protein. Serotyping is dependent on heat-labile K agglutinogens. Of 14 agglutinogens, six are specific to *B. pertussis*. Serotypes vary geographically and

over time.

B. pertussis produces an array of biologically active substances, many of which are postulated to have a role in disease and immunity. After aerosol acquisition, **filamentous hemagglutinin** (FHA), some **agglutinogens** (especially fimbriae [Fim] types 2 and 3), and a 69-kd nonfimbrial surface protein called **pertactin** (Pn) are important for attachment to ciliated respiratory epithelial cells. **Tracheal cytotoxin**, adenylate cyclase, and PT appear to inhibit clearance of organisms. Tracheal cytotoxin, dermonecrotic factor, and adenylate cyclase are postulated to be predominantly responsible for the local epithelial damage that produces respiratory symptoms and facilitates absorption of PT. PT has numerous proven biologic activities (e.g., histamine sensitivity, insulin secretion, leukocyte dysfunction), some of which may account for systemic manifestations of disease. PT causes lymphocytosis immediately in experimental animals by rerouting lymphocytes to remain in the circulating blood pool. PT appears to have a central but not a singular role in pathogenesis.

Clinical Manifestations.

Classically, pertussis is a 6-wk disease, divided into catarrhal, paroxysmal, and convalescent stages. The **catarrhal stage** begins after an incubation period ranging from 3–12 days with nondistinctive symptoms of congestion and rhinorrhea variably accompanied by low-grade fever, sneezing, lacrimation, and conjunctival suffusion. As initial symptoms wane, coughing marks the onset of the **paroxysmal stage**. The cough is first as a dry, intermittent, irritative hack and evolves into the inexorable paroxysms that are the hallmark of pertussis. Infants <3 mo do not display classical stages. After the most insignificant startle from a draught, light, sound, sucking, or stretching, a well-appearing young infant begins to choke, gasp, and flail extremities, with face reddened. Cough (expiratory grunt) may not be prominent. **Whoop** (forceful inspiratory gasp) infrequently occurs in infants <3 mo of age who are exhausted or lack muscular strength to create sudden negative intrathoracic pressure. A well-appearing, playful toddler with similarly insignificant provocation suddenly expresses an anxious aura and may clutch a parent or comforting adult before beginning a machine-gun burst of uninterrupted coughs, chin and chest held forward, tongue protruding maximally, eyes bulging and watering, face purple, until coughing ceases and a loud whoop follows as inspired air traverses the still partially closed airway. Adults describe a sudden feeling of strangulation followed by uninterrupted coughs, feeling of suffocation, bursting headache, diminished awareness, and then a gasping breath, usually without a whoop. Post-tussive emesis is common in pertussis at all ages and is a specific clue to the diagnosis in adolescents and adults. Post-tussive exhaustion is universal. The number and severity of paroxysms progress over days to a week (more rapidly in young infants) and remain at that plateau for days to weeks (longer in young infants). At the peak of the paroxysmal stage, patients may have more than one episode hourly. As paroxysmal stage fades into the **convalescent stage**, the number, severity, and duration of episodes diminish. Paradoxically in infants, cough and whoops may become louder and more classic in convalescence.

Immunized children have foreshortening of all stages of pertussis. Adults have no distinct stages. In infants younger than 3 mo, the catarrhal phase is usually a few days or not recognized at all when apnea, choking, or gasping cough herald the onset of disease; convalescence includes intermittent paroxysmal coughing throughout the 1st year of life, including “exacerbations” with subsequent respiratory illnesses; these are not due to recurrent infection or reactivation of *B. pertussis*.

Findings on physical examination generally are uninformative. Signs of lower respiratory tract disease are not expected. Conjunctival hemorrhages and petechiae on the upper body are common.

Diagnosis.
